Preface

In the last decade, many textbooks of pediatrics have been published in India. However, most were targeted towards undergraduates and general practitioners. The number of students opting for postgraduate courses in pediatrics is on the rise. Currently, most postgraduates in pediatrics augment their knowledge by reading and referencing to textbooks published abroad. Many of the Western textbooks are very detailed and provide an important amalgamation of clinical pediatrics with the major advances in genetics, genomics, physiology, diagnosis, imaging, and therapeutics. However, the “state-of-the-art” on the care of the normal and ill neonate, child, or adolescent as presented in these textbooks differ from that practiced in India or South Asia. While these books provide a detailed description of most disorders seen in children, they unfortunately do not provide both evidence-based medicine and astute personal clinical experiences from India. The focus is missing on the core issues relevant in the Indian context, i.e., growth, nutrition, immunization, development, newborn and adolescent health, and programmatic and social issues in child health. The need for a comprehensive postgraduate textbook, which can be adapted to Indian needs, has been recognized and expressed for some time now.

Rapid strides in medicine and technological advances in biological sciences were witnessed in the last decade. Advances in preventive and therapeutic care have opened new prospects for care of children. However, substantial improvements in quality of life have been limited to those with access to healthcare. Poverty, ignorance, war, bioterrorism, misplaced priorities and the lack of political will have prevented many children throughout the world, benefitting from these significant advances. Despite advances in infectious diseases, newer vaccines and preventive neonatal care, mortality and morbidity continue to be unacceptably high. Our priorities for care of children are often different from the developed world. Also, medical advances and good clinical practice must always be coupled with effective advocacy. These aspects need to be addressed in a postgraduate textbook, as current postgraduates are the future decision makers in our country.

It is our earnest wish and hope that the postgraduate textbook will help to fill the long-felt vacuum. It attempts to provide the essential information that postgraduates throughout India need to capture to effectively address the health problems that our children and youth may face in the times to come. Our objective is to be comprehensive yet concise and reader friendly, embracing both the new advances in science as well as the time-honored art of pediatric practice. Both Indian and international experts in respective fields have provided the details that have been further scrutinized for exposition and usefulness to pediatric postgraduates by a chosen team of eminent academicians. We have liberally included tables, line diagrams, images, clinical photographs, illustrative figures, flow charts and algorithms in the main text. The book is divided into 10 major Parts and further arranged into 51 Sections and Annexures to cover all aspects of postgraduate pediatric curriculum. Themes which have major public health relevance for India are extensively covered. It is almost impossible to cover all pediatric problems with the same degree of detail, and hence a careful balance has been made in the details of description of diseases and their management to the needs of the students, and to keep the book to a manageable size. Summary points “In A Nutshell” are provided at the end of each chapter. Selected recent references—mostly leading articles, reviews and position statements—are provided for more detailed information, if desired by the student or the teacher.

Some kind of overlap is unavoidable in a book of this magnitude, with 725 plus minds working on more than 600 chapters simultaneously. We have strived hard to minimize it. We have also tried our best to keep all the chapters on an even keel despite the unavoidable diversity of disciplines, thoughts, experience, and expressive capabilities of the distinguished authors and section editors, from all over the globe. The book would not have been possible but for the support that we received from these erudite contributors. We are indebted to them for their knowledge, introspection, and judgment during the entire process. Together we have worked hard to produce a compilation that will be helpful to those who desire to learn more about child health in India and thus provide better care for children.

Acknowledgments

ACKNOWLEDGMENTS FROM AUTHORS

2.1 Gene, Genome and Genetic Basis of Diseases

I have written similar chapters on basics of genetics and molecular medicine for three editions (8th, 9th and 10th) of the *API Textbook of Medicine* published by the Association of Physicians of India, Mumbai. I am grateful to Ms Smrithi for drawing the figures in this chapter.
Girisha KM

3.1.1 Inborn Errors of Metabolism

We are grateful to our patients, their families, students, residents and colleagues for their help. We thank Dr Charushree Prasad for critically reviewing the chapter and providing suggestions.

Chitra Prasad, CA Rupar

9.1 Poisoning

I wish to acknowledge the help and support given to me by Dr Paul Nixon.

P Ramesh Menon

12.2 Assessment of the Newborn

We acknowledge the efforts of Dr Aliza Mittal in taking clinical photographs for the chapter.

Harish Chellani, Sugandha Arya

18.5 CNS Malformations

We gratefully acknowledge the help of Professors Sandeep Agarwal and M Srinivas by contributing the photographs for this chapter.

Nidhi Sugandhi, Veereshwar Bhatnagar

23.1 Basic Concepts of Vaccination

I have immensely benefitted from the interactions with many eminent vaccine experts, epidemiologists, academicians and public health program managers. A few of the concepts presented in this chapter could have been (knowingly and unknowingly) borrowed, developed and influenced by my interactions with national and international experts in these areas. I would like to acknowledge their teaching and influence. The opinions expressed in the chapter are solely of mine and should not be attributed to any institution/organization; I have been affiliated in the past or at present.

Chandrakant Lahariya

23.5 Adverse Events Following Immunization

I have borrowed heavily from my earlier publication (Vashishtha VM, Kalra A. Adverse Events following Immunization (AEFI), Vaccine Safety and Misinformation against Vaccination. Mumbai: Tree Life Media; 2014.) after due permission from the authors.

Ajay Kalra

23.13 Typhoid Fever Vaccines

We would like to thank Dr Leon Ochiai for the continuous guidance and encouragement and Dr Vittal Mogasale for constructive suggestions during the review process.

Sushant Sahastrabuddhe, Mohammad Imran Khan

31.19 HIV and Acquired Immunodeficiency Syndrome

We thank Dr Shubhangi Parkar, Dean (Incharge) of Seth GS Medical College and KEM Hospital, for granting permission to publish this manuscript.

Milind S Tullu, Chhaya Divecha

37.1 Applied Anatomy and Physiology of Liver and Biliary Tract

Special thanks to Dr Vijayshri Bhide, GI and Liver Pathologist, Department of Pathology, Deenanath Mangeshkar Hospital, Pune for sharing liver histology pictures.

Vishnu Biradar

40.39 Surgical Considerations in Congenital Heart Diseases

Acknowledgement and thanks to my teachers for their contribution and help me in gaining appropriate knowledge and skills to choose, offer and perform the correct operative procedure to scores of unfortunate children born with simple and complex congenital heart defects.

R Benedict Raj

40.40 Preventive Cardiology in the Young

This publication was made possible by grant number 1 D43 HD065249 from the Fogarty International Center and the Eunice Kennedy Shriver National Institute of Child Health and Human Development at the National Institutes of Health.

S Sivasankaran

42.11 Status Epilepticus

We wish to acknowledge the help and support provided by Lisa Garrity, Pharm D.

Ravindra Arya, Katrina Peariso

42.24 Childhood Ataxia

I wish to acknowledge that a significant part of the discussion on genetic and inherited metabolic disorders associated with ataxia was included in a prior work on the same subject published for e-medicine. The material has been modified considerably to fit into a pertinent discussion on childhood ataxia. I also wish to acknowledge and thank contributors to the prior work; Professor Cheryl Greenberg (MD FRCPC), Division of Genetics and Metabolism, University of Manitoba; Dr Chitra Prasad (MD FRCPC FCCMG), Genetics and Metabolic Disorders, Program of South-Western Ontario; Professor M Jog (MD FRCPC), Division of Clinical Neurosciences, University of Western Ontario.

Asuri N Prasad

47.1 Common Visual Problems

I wish to acknowledge the contribution of Dr Ankush Mutreja in preparation of Flow charts 1 to 5 included in this chapter.

Kirti Singh

48.11 Cutaneous Manifestations of Collagen Vascular Diseases

I acknowledge Dr Ipsa Niyant Pandya, postgraduate student, Department of Skin and Veneral Diseases, Baroda Medical College, Vadodara, Gujarat for her invaluable contribution.

Yogesh S Marfatia

FROM THE EDITORIAL DESK

Ms Anju Kumari: Secretarial assistance.

Dr Sakshi Sachdeva: Editorial assistance.

We would like to extend our thanks and appreciation to Shri Jitendar P Vij (Group Chairman) and Mr Ankit Vij (Group President) for their vision and belief in this project; Mr Tarun Duneja (Director-Publishing), Mr KK Raman (Production Manager), Ms Samina Khan (Exec. Assistant to Director-Publishing), Mr Sunil Kumar Dogra (Production Executive) and Mr Neelambar Pant (Production Coordinator), for their unflinching support and tireless work. We would also like to thank the entire staff of M/s Jaypee Brothers Medical Publishers (P) Ltd, New Delhi, India, especially Ms Shalu Mann (Medical Editor); Mr Gurnam Singh (Sr Proofreader); Mr Sarvesh Kumar, Ms Kamlesh Rawat, Mr Gyanendra Kumar (Proofreaders); Mr Rajesh Kumar, Mrs Yashu Kapoor, Mr Rakesh Kumar (Typesetters); Mr Satender Singh, Mr Sumit Kumar, Mr Rohan Prasad (Graphic Designers); and Mr Joginder Kumar for delivery of the proofs.

Contents

Volume 1: General Pediatrics and Neonatology

PART I: Pediatrics—Yesterday, Today, Tomorrow

Section 1: INTRODUCTION TO PEDIATRICS

Section Editors Piyush Gupta, PSN Menon

1.1	Evolution of Pediatrics	1
	<i>KN Agarwal</i>	
1.2	20 Milestones in the History of Pediatrics	5
	<i>Santosh K Bhargava</i>	
1.3	Status of Child Health	8
	<i>RN Srivastava</i>	
1.4	Millennium Development Goals for Child Health	11
	<i>Raju C Shah, Pratima Shah, Kunal Ahya</i>	
1.5	Evidence-based Care in Pediatrics	16
	<i>Joseph L Mathew</i>	

PART II: Basic Sciences as Applied to Pediatrics

Section 2: GENETICS AND GENETIC DISORDERS

Section Editor Shubha R Phadke

2.1	Gene, Genome and Genetic Basis of Diseases	20
	<i>Girisha KM</i>	
2.2	Patterns of Inheritance	26
	<i>Prajnya Ranganath, Shubha R Phadke</i>	
2.3	Clinical Dysmorphology: An Approach to Bedside Diagnosis	33
	<i>Ratna Dua Puri</i>	
2.4	Chromosomal Disorders	39
	<i>Shagun Aggarwal, Ashwin Dalal</i>	
2.5	Management of Genetic Disorders and Genetic Counseling	49
	<i>Shubha R Phadke</i>	
2.6	Prevention of Genetic Disorders	56
	<i>Neerja Gupta, Madhulika Kabra</i>	

Section 3: METABOLIC DISORDERS

Section Editors Madhulika Kabra, Neerja Gupta

3.1	Approach to Inborn Errors of Metabolism	61
	<i>Chitra Prasad, CA Rupar</i>	
3.2	Defects of Amino Acid Metabolism	70
	<i>Anil B Jalan, Ketki V Kudalkar</i>	

3.3	Urea Cycle Disorders	79
	<i>Sunita Bijarnia-Mahay</i>	
3.4	Organic Acidemias	86
	<i>Neerja Gupta</i>	
3.5	Fatty Acid Oxidation Defects	93
	<i>Manisha Goyal, Seema Kapoor</i>	
3.6	Mitochondrial Disorders	98
	<i>Sheffali Gulati, Biswaroop Chakrabarty</i>	
3.7	Peroxisomal Disorders	103
	<i>Madhulika Kabra, Neerja Gupta</i>	
3.8	Lysosomal Storage Disorders	106
	<i>IC Verma</i>	
3.9	GM1 and GM2 Gangliosidosis	114
	<i>Parag M Tamhankar</i>	
3.10	Gaucher Disease	117
	<i>Mamta Muranjan</i>	
3.11	Niemann-Pick Disease	127
	<i>Ashwin Dalal</i>	
3.12	Fabry Disease	131
	<i>Ratna Dua Puri</i>	
3.13	Defects of Carbohydrate Metabolism	135
	<i>Kausik Mandal</i>	
3.14	Glycogen Storage Diseases	141
	<i>Priya S Kishnani, Stephanie Austin</i>	
3.15	Pompe Disease	145
	<i>Mari Mori, Priya S Kishnani</i>	
3.16	Mucopolysaccharidoses	149
	<i>Girisha KM</i>	
3.17	Approach to Hypoglycemia	154
	<i>Meenakshi Bothra, Vandana Jain</i>	
3.18	Porphyrias	161
	<i>Meenal Agarwal, Shubha R Phadke</i>	
3.19	Newborn Screening	165
	<i>Seema Kapoor, Madhulika Kabra</i>	

Section 4: IMMUNITY, IMMUNE DISORDERS AND ALLERGY

Section Editors Surjit Singh, Amit Rawat

4.1	Basics of Immunology	169
	<i>Amit Rawat, Biman Saikia</i>	

4.2	Laboratory Diagnosis of Immune-mediated Diseases <i>Biman Saikia, Deepti Suri</i>	176	7.4	Pediatric Advanced Life Support (PALS) <i>Banani Poddar</i>	253
4.3	Primary Immunodeficiency Disorders <i>Manisha Madkaikar</i>	184	Section 8: INTENSIVE CARE		
4.4	Therapy for Primary Immunodeficiency Disorders <i>Revathi Raj, Surjit Singh</i>	191	Section Editor Rakesh Lodha		
4.5	Intravenous Immunoglobulin <i>Sujoy Khan, Surjit Singh</i>	193	8.1	Pediatric Intensive Care Unit <i>Dhiren Gupta, Neeraj Gupta, Manpreet Sethi</i>	264
4.6	Approach to a Child with Allergic Disorder <i>H Paramesh</i>	198	8.2	Shock <i>Srinivas Murthy, Niranjan Kissoon</i>	268
Section 5: FLUID AND ELECTROLYTES			8.3	Acute Respiratory Distress Syndrome <i>Venkat Shankar</i>	274
Section Editor Rakesh Lodha			8.4	Respiratory Failure <i>Lokesh Guglani</i>	281
5.1	Body Fluids <i>Raghuvamsi Chaitra, Suchitra Ranjit</i>	201	8.5	Mechanical Ventilation <i>Dinesh Raj, Rakesh Lodha</i>	288
5.2	Maintenance Fluid Therapy <i>Banani Poddar, Kirti M Naranje</i>	206	8.6	Sedation and Analgesia <i>Venkat Shankar</i>	297
5.3	Acid-Base Equilibrium <i>Dinesh Raj, Rakesh Lodha</i>	210	Section 9: POISONING AND ENVENOMATION		
5.4	Abnormalities of Acid-Base Balance <i>Dinesh Raj, Rakesh Lodha</i>	214	Section Editor Rakesh Lodha		
5.5	Sodium and Related Disorders <i>Andrew C Argent, Mignon I McCulloch</i>	220	9.1	Clinical Approach to a Poisoned Child <i>P Ramesh Menon</i>	302
5.6	Potassium <i>Virendra Kumar</i>	225	9.2	Poisonings by Common Drugs <i>Indumathy Santhanam, Sharada Sathish</i>	308
5.7	Magnesium Balance <i>Virendra Kumar</i>	229	9.3	Hydrocarbon Poisoning <i>Jayashree M, Karthi N</i>	315
Section 6: DRUGS AND THERAPEUTICS			9.4	Poisoning in the Household <i>Narayanan P, Harikrishnan KN</i>	318
Section Editor Sandeep B Bavdekar			9.5	Corrosive Poisoning <i>Urmila Jhamb</i>	326
6.1	Principles of Drug Therapy <i>Sandeep B Bavdekar</i>	231	9.6	Snakebite <i>S Mahadevan, R Ramesh Kumar</i>	331
6.2	Administration of Medications <i>Jeerson C Unni</i>	236	9.7	Scorpion Sting <i>S Mahadevan, R Ramesh Kumar</i>	341
PART III: Intensive Care and Emergencies			Section 10: CHILDHOOD INJURIES		
Section 7: ACUTELY ILL CHILD AND RESUSCITATION			Section Editor Rakesh Lodha		
Section Editor Rakesh Lodha			10.1	Trauma: Stabilization, Triage and Transport <i>Shruti Kant, Manu Madhok</i>	348
7.1	Assessment and Triage <i>Jayashree M, Sunit Singh</i>	241	10.2	Drowning/Submersion Injuries <i>Arun Bansal</i>	354
7.2	Cardiopulmonary Resuscitation <i>Utpal Bhalala, Vijay Srinivasan</i>	245	10.3	Animal Related Injuries <i>Arun Kumar Baranwal</i>	357
7.3	Basic Life Support (BLS) <i>Shalu Gupta</i>	249	10.4	Pediatric Burns <i>K Mathangi Ramakrishnan, V Jayaraman, T Mathivanan, V Srinivasan</i>	361
			10.5	Cold Injuries <i>Manu Madhok, Shruti Kant</i>	370

PART IV: The Newborn Infant

Section 11: NEONATAL PHYSIOLOGY AND ORGANIZATION OF CARE

Section Editor Siddarth Ramji

11.1	Fetal Physiology and Growth	376
	<i>Deepak Chawla</i>	
11.2	Maternal Influence on the Fetus	380
	<i>Jayashree Mondkar, Swati Manerkar</i>	
11.3	Transition of the Fetus to Newborn	383
	<i>Siddarth Ramji</i>	
11.4	Neonatal Mortality and Morbidities: An Overview	386
	<i>Aparna Chandrasekaran, M Jeeva Sankar</i>	
11.5	Organization of Neonatal Care	392
	<i>Subhash Chandra Shaw, Vinod K Paul</i>	

Section 12: NORMAL NEWBORN

Section Editor Siddarth Ramji

12.1	Delivery Room Care of the Newborn	396
	<i>Siddarth Ramji</i>	
12.2	Assessment of the Newborn	401
	<i>Harish Chellani, Sugandha Arya</i>	
12.3	Care of the Normal Newborn	408
	<i>Somashekhar Nimbalkar</i>	
12.4	Maintenance of Temperature	412
	<i>Suksham Jain, Ravish Singh</i>	
12.5	Breastfeeding and Lactation Management	417
	<i>NB Mathur</i>	

Section 13: DISORDERS OF WEIGHT AND GESTATION

Section Editor Siddarth Ramji

13.1	Low Birthweight: Classification and Etiology	422
	<i>Ruchi Nimish Nanavati</i>	
13.2	Prematurity and Intrauterine Growth Restriction	427
	<i>Ashok Kumar, Sriparna Basu</i>	
13.3	Feeding of Low Birthweight	432
	<i>Kanya Mukhopadhyay</i>	
13.4	Long-term Outcome of Low Birthweight	437
	<i>Suman Rao PN, Nikhil Kulkarni</i>	
13.5	Postmaturity	442
	<i>Reeta Bora, Pranay Phukan</i>	
13.6	Large for Gestational Age	445
	<i>Rhishikesh Thakre</i>	
13.7	Multiple Gestations	449
	<i>Mamta Jajoo</i>	

Section 14: HIGH-RISK NEWBORN

Section Editor Siddarth Ramji

14.1	Recognition of High-Risk Neonate	453
	<i>Niranjan Thomas, Vijay Gupta</i>	
14.2	Birth Injuries	462
	<i>Neeraj Gupta</i>	
14.3	Jaundice in the Newborn	469
	<i>Sheila S Mathai, Kannan Venkatnarayan</i>	
14.4	Infant of Diabetic Mother	479
	<i>Srinivas Murki, Tejo Oleti Pratap</i>	
14.5	Neonatal Hypoglycemia	483
	<i>Shiv Sajan Saini, Praveen Kumar</i>	
14.6	Anemia and Polycythemia	489
	<i>Venkataseshan Sundaram, Bikramjit Das</i>	
14.7	The Bleeding Neonate	498
	<i>Arun Kumar</i>	
14.8	Hemorrhagic Disease of the Newborn	503
	<i>JN Sharma</i>	
14.9	Thrombocytopenia in the Newborn	506
	<i>Pradeep Sharma</i>	
14.10	Cyanosis in the Newborn	508
	<i>K Anil Kuruvilla, Vijay Gupta</i>	
14.11	Necrotizing Enterocolitis	515
	<i>Krishna Kumar Diwakar</i>	
14.12	Retinopathy of Prematurity	521
	<i>Ashish Jain, Veeraraja B Sathenahalli, Karobi Lahiri Coutinho</i>	
14.13	Neonatal Transport	527
	<i>Neelam Kler, Anup Thakur</i>	
14.14	Follow-Up of the High-Risk Neonate	532
	<i>Shuchita Gupta</i>	

Section 15: NEONATAL INFECTIONS

Section Editor Siddarth Ramji

15.1	Neonatal Sepsis	540
	<i>Suman Chaurasia, Ramesh Agarwal</i>	
15.2	Superficial Infections	547
	<i>Sriparna Basu, Ashok Kumar</i>	
15.3	Meningitis in the Newborn	552
	<i>Kumutha Jayaraman, Manigandan Chandrasekaran</i>	
15.4	Deep-seated Infections	559
	<i>Kumutha Jayaraman, Manigandan Chandrasekaran</i>	
15.5	Neonatal Tetanus	563
	<i>Mala Kumar, Shalini Tripathi</i>	
15.6	Intrauterine Infections	565
	<i>Sriparna Basu, Ashok Kumar</i>	

Section 16: NEUROLOGICAL PROBLEMS OF THE NEWBORN INFANT

Section Editor Siddarth Ramji

16.1	Seizures in the Neonates	572
	<i>Amit Upadhyay, Pranjali Saxena</i>	
16.2	Hypoxic Ischemic Encephalopathy	578
	<i>B Vishnu Bhat, B Adhisivam</i>	
16.3	Intraventricular Hemorrhage and White Matter Injury	585
	<i>Shamik Trivedi, Amit M Mathur</i>	

Section 17: RESPIRATORY PROBLEMS OF THE NEWBORN INFANT

Section Editor Siddarth Ramji

17.1	Approach to a Neonate with Respiratory Distress	592
	<i>Swarna Rekha Bhat</i>	
17.2	Neonatal Apnea	596
	<i>Manoj Modi</i>	
17.3	Neonatal Ventilation	600
	<i>Sourabh Dutta</i>	
17.4	Hyaline Membrane Disease	605
	<i>Praveen Kumar, Anuj Bhatti</i>	
17.5	Transient Tachypnea of the Newborn	612
	<i>Srinivas Murki</i>	
17.6	Meconium Aspiration Syndrome	614
	<i>Naveen Jain</i>	
17.7	Pulmonary Air Leaks in the Newborn	617
	<i>Manish Balde, Sanjay Wazir</i>	
17.8	Persistent Pulmonary Hypertension (PPHN)	622
	<i>Neeraj Gupta</i>	
17.9	Pulmonary Hemorrhage	629
	<i>Emily F Fishman, Rakesh Rao</i>	
17.10	Bronchopulmonary Dysplasia in Newborn	635
	<i>Samir Gupta, Sunil K Sinha</i>	

Section 18: NEONATAL MALFORMATIONS

Section Editor Siddarth Ramji

18.1	Esophageal Atresia and Tracheoesophageal Fistula	640
	<i>Yogesh Kumar Sarin, Shalini Sinha</i>	
18.2	Diaphragmatic Hernia and Eventration	645
	<i>Shalini Sinha, Yogesh Kumar Sarin</i>	
18.3	Gastrointestinal and Abdominal Malformations	650
	<i>Satish Kumar Aggarwal</i>	
18.4	Genitourinary Malformations	661
	<i>Satish Kumar Aggarwal</i>	
18.5	CNS Malformations	670
	<i>Nidhi Sugandhi, Veereshwar Bhatnagar</i>	

PART V: The Childhood Years

Section 19: GROWTH: NORMAL AND ABNORMAL

Section Editor Anju Seth

19.1	Normal Growth	680
	<i>Ruchi Mishra, Vandana Jain</i>	
19.2	Factors Affecting Growth	684
	<i>Devi Dayal, Anil Kumar Bhalla</i>	
19.3	Assessment of Physical Growth	688
	<i>Anju Seth, Rajni Sharma</i>	
19.4	Dental Development and Anomalies	713
	<i>Sunanda Roychoudhury, Shakil Ahmed Nagori, Ajoy Roychoudhury</i>	
19.5	Bone Age and Predicted Final Height	723
	<i>M Vijayakumar, Anju Seth</i>	
19.6	Failure to Thrive	726
	<i>Sudha Rao Chandrashekhar</i>	
19.7	Overweight and Obesity	733
	<i>Rajesh Khadgawat, Aashima Dabas</i>	
19.8	Abnormalities of Stature	739
	<i>Senthil Senniappan, Leena Patel</i>	

Section 20: DEVELOPMENT AND DEVELOPMENTAL DELAY

Section Editors Anand Pandit, Sudha Chaudhari

20.1	Introduction to Development, Laws of Development, and Factors Affecting Development	749
	<i>Satnam Kaur</i>	
20.2	Normal Development	753
	<i>Ujjwal Nene</i>	
20.3	Approach to Diagnosis of Developmental Delay: Developmental Screening and Surveillance	759
	<i>Sudha Chaudhari</i>	
20.4	Global Developmental Delay	766
	<i>Madhuri Kulkarni, Mona P Gajre</i>	
20.5	Intellectual Disability	770
	<i>Suja Koshy</i>	
20.6	Visual Impairment	780
	<i>Nikhil Rishikeshi, Sucheta Kulkarni</i>	
20.7	Hearing Impairment	782
	<i>Neelam Vaid</i>	
20.8	Cerebral Palsy	787
	<i>Sharmila Banerjee Mukherjee</i>	

Section 21: BEHAVIOR AND LEARNING

Section Editors Monica Juneja, Devendra Mishra

21.1	Moral Development	800
	<i>Prahbjot Malhi, Rajalakshmi Iyer</i>	
21.2	Sleep Hygiene and Disorders of Sleep	803
	<i>Suresh Kotagal</i>	
21.3	Common Behavioral Problems	809
	<i>Praveen Suman</i>	
21.4	Enuresis and Encopresis	813
	<i>Piyush Gupta, Ruchi Mishra</i>	
21.5	Breath-Holding Spells	818
	<i>Sumaira Khalil, Devendra Mishra</i>	
21.6	Common Speech, Language and Communication Disorders	821
	<i>Prathibha Karanth</i>	
21.7	Autism Spectrum Disorder	827
	<i>Monica Juneja, Rahul Jain</i>	
21.8	Rett Syndrome	833
	<i>Monica Juneja, Rajni Khajuria</i>	
21.9	Attention Deficit Hyperactivity Disorder	836
	<i>Rajesh Sagar, Rohit Verma</i>	
21.10	Oppositional Defiant and Conduct Disorders	843
	<i>Rajesh Sagar, Rajeew Ranjan</i>	
21.11	Learning Disabilities	847
	<i>Nandini Mundkur, Chitra Sankar</i>	
21.12	Anorexia Nervosa and Bulimia	851
	<i>Koushik Sinha Deb, Rajesh Sagar</i>	
21.13	Anxiety Disorders	854
	<i>Shoba Srinath, Preeti Kandasamy</i>	
21.14	Evaluation of Mental Well-Being	856
	<i>Manju Mehta, Sneha Kapoor</i>	
21.15	Management of Psychological Illness	858
	<i>Paul Russell</i>	

Section 22: NUTRITION AND NUTRITIONAL DISORDERS

Section Editors KE Elizabeth, Piyush Gupta

22.1	Nutrient Groups and Nutritional Requirements	863
	<i>KE Elizabeth, S Bindusha</i>	
22.2	Nutritive Values of Foods	868
	<i>Neetu Sharma, Piyush Gupta</i>	
22.3	Infant and Young Child Feeding	877
	<i>JP Dadhich</i>	
22.4	Feeding During Childhood and Food Allergy	881
	<i>KE Elizabeth, S Bindusha</i>	
22.5	Undernutrition: Prevalence and Etiology	884
	<i>Piyush Gupta, Neetu Sharma</i>	

22.6	Pathophysiology of Undernutrition	891
	<i>OP Mishra</i>	
22.7	Protein Energy Malnutrition	894
	<i>KE Elizabeth</i>	
22.8	Severe Acute Malnutrition	899
	<i>Praveen Kumar, Preeti Singh</i>	
22.9	Vitamin A	907
	<i>Neetu Sharma, Piyush Gupta</i>	
22.10	Vitamin B Complex Deficiency	913
	<i>Vineeta Gupta</i>	
22.11	Vitamin C and Scurvy	917
	<i>Tejinder Singh, Shaveta Kundra</i>	
22.12	Vitamin D, Nutritional Rickets and Hypervitaminosis D	920
	<i>S Balasubramanian</i>	
22.13	Iodine Deficiency Disorders	925
	<i>Umesh Kapil, Neha Sareen</i>	
22.14	Zinc in Child Health	928
	<i>Shashi Ajit Chiplonkar</i>	
22.15	Trace Elements in Nutrition and Health	932
	<i>P Leelakumari, KE Elizabeth</i>	
22.16	Fluorosis	935
	<i>Sunil Kumar Gupta</i>	
22.17	Enteral and Parenteral Nutrition	941
	<i>Ashish Bavdekar</i>	
22.18	Nutrition in the 21st Century	946
	<i>Gouri Rao Passi, Piyush Gupta</i>	
22.19	National Nutrition Programs	950
	<i>Dipty Jain, Veena Kamat, Vinit Warthe</i>	

Section 23: IMMUNIZATION

Section Editors Vipin M Vashishtha, Ajay Kalra

23.1	Basic Concepts of Vaccination	953
	<i>Chandrakant Lahariya</i>	
23.2	Vaccine Administration Practices	962
	<i>Satish V Pandya</i>	
23.3	Scheduling of Vaccines	966
	<i>Vipin M Vashishtha</i>	
23.4	Vaccine Storage and Cold Chain	972
	<i>Karan Singh Sagar, Manish Jain</i>	
23.5	Adverse Events Following Immunization	978
	<i>Ajay Kalra</i>	
23.6	BCG Vaccine	982
	<i>Sangeeta Sharma</i>	
23.7	Poliovirus Vaccines	986
	<i>Puneet Kumar, Vipin M Vashishtha</i>	
23.8	Diphtheria, Tetanus and Pertussis Vaccines	991
	<i>Puneet Kumar, Vipin M Vashishtha</i>	

23.9	Hepatitis B Vaccine <i>Ajay Kalra</i>	995
23.10	<i>Haemophilus Influenzae</i> Type B (HIB) Vaccines <i>AK Patwari</i>	998
23.11	Measles Vaccine <i>Sumit Mehndiratta, AP Dubey</i>	1000
23.12	Rubella and Mumps Vaccines <i>Aashima Dabas, Piyush Gupta</i>	1002
23.13	Typhoid Fever Vaccines <i>Sushant Sahastrabudde, Mohammad Imran Khan</i>	1005
23.14	Japanese Encephalitis Vaccine <i>VG Ramachandran</i>	1009
23.15	Rabies Vaccines <i>Anuradha Bose</i>	1011
23.16	Pneumococcal Vaccines <i>Puneet Kumar, Vipin M Vashishtha</i>	1014
23.17	Rotavirus Vaccines <i>Gagandeep Kang</i>	1018
23.18	Cholera Vaccines <i>Monjori Mitra</i>	1020
23.19	Varicella Vaccine <i>Rakesh Kumar</i>	1022
23.20	Hepatitis A Vaccine <i>Vikram Gagneja, AJ Chitkara</i>	1024
23.21	Meningococcal Vaccine <i>Jaydeep Choudhury</i>	1027
23.22	Seasonal and Pandemic Influenza Vaccines <i>Shobha Broor</i>	1029
23.23	Human Papillomavirus Vaccines <i>Srinivas G Kasi</i>	1034
23.24	Yellow Fever Vaccine <i>Parang N Mehta</i>	1038
23.25	Combination Vaccines <i>Niranjan Shendurnikar, Sheila Aiyer</i>	1040
23.26	Immunization in Special Situations <i>Panna Choudhury</i>	1043

PART VI: The Adolescent

Section 24: ADOLESCENT DEVELOPMENT

Section Editor MKC Nair

24.1	Adolescence and Adolescent <i>MKC Nair, Paul Russell</i>	1047
24.2	Sexual Development and Sexuality <i>Chandrika Rao</i>	1051
24.3	Psychosocial Development <i>Yamuna S</i>	1055

Section 25: HEALTH ISSUES IN ADOLESCENCE

Section Editor MKC Nair

25.1	Factors Influencing Adolescent Health <i>Sukanta Chatterjee</i>	1061
25.2	Adolescent Nutrition <i>Preeti M Galagali</i>	1067
25.3	Mental Health <i>Priya Mary Mammen</i>	1074
25.4	Injuries, Violence and Suicide <i>Srikanta Basu</i>	1080
25.5	Menstrual Disorders and Polycystic Ovary Syndrome <i>Amita Suneja, Richa Aggarwal</i>	1087
25.6	Sexually Transmitted Infections <i>Newton Luiz</i>	1095
25.7	Teenage Pregnancy <i>Amita Suneja, Richa Aggarwal</i>	1100

Section 26: CARE OF ADOLESCENTS

Section Editor MKC Nair

26.1	Promoting Health of Adolescents <i>Harish K Pemde, Kamlesh Harish</i>	1102
26.2	Adolescent Counseling <i>Atul M Kanikar</i>	1107
26.3	Adolescent Friendly Health Services <i>Rajesh Mehta, Neena Raina, Patanjali Dev Nayar</i>	1115

Volume 2: Infections and Systemic Disorders

PART VII: Infectious Diseases

Section 27: BASIC CONCEPTS

Section Editors Jaydeep Choudhury, Piyush Gupta

27.1	Epidemiology of Infectious Diseases <i>VG Ramachandran, Piyush Gupta</i>	1119	27.2	Laboratory Diagnosis of Infection <i>Sankar Sengupta</i>	1125
			27.3	Antimicrobial Resistance <i>Anuradha De</i>	1129
			27.4	Infection Control and Prevention <i>Jaydeep Choudhury</i>	1136

Section 28: FEVER

Section Editor Piyush Gupta

28.1	Approach to a Child with Fever <i>Bhavna Dhingra, Piyush Gupta</i>	1140
28.2	Fever: General Principles of Management <i>Piyush Gupta, Bhavna Dhingra</i>	1143
28.3	Fever without Focus <i>Piyush Gupta, Bhavna Dhingra</i>	1146
28.4	Fever of Unknown Origin <i>Bhavna Dhingra, Piyush Gupta</i>	1149

Section 29: BACTERIAL INFECTIONS

Section Editors Jaydeep Choudhury, Piyush Gupta

29.1	Natural History of Bacterial Infection <i>VG Ramachandran, Piyush Gupta</i>	1152
29.2	Principles of Antibiotic Therapy <i>Anita Shet</i>	1155
29.3	Diphtheria <i>Prerna Batra, Piyush Gupta</i>	1162
29.4	Pertussis <i>Piyush Gupta, Prerna Batra</i>	1166
29.5	Tetanus <i>Jaydeep Choudhury</i>	1169
29.6	Typhoid Fever <i>Apurba Ghosh, Monjori Mitra</i>	1171
29.7	Nontyphoidal Salmonellosis <i>Thangavelu Sangaralingam, Janani Ravi</i>	1176
29.8	<i>Haemophilus influenzae</i> B Infections <i>Somu Sivabalan</i>	1179
29.9	Pneumococcal Infections <i>Meenu Singh, Nishant Jaiswal</i>	1182
29.10	Streptococcal Infections <i>Pramod Sharma</i>	1185
29.11	Staphylococcal Infections <i>Zaki Syed</i>	1188
29.12	<i>Neisseria</i> Infections <i>Vidushi Mahajan</i>	1193
29.13	<i>Pseudomonas</i> Infections <i>Nupur Ganguly</i>	1196
29.14	Leptospirosis <i>Janani Sankar</i>	1198
29.15	Plague <i>Baldev S Prajapati, Rajal B Prajapati, Piyush Gupta</i>	1201
29.16	Brucellosis <i>Sriram Krishnamurthy</i>	1204

29.17	Relapsing Fever <i>P Ramachandran</i>	1207
29.18	Lyme Disease <i>P Ramachandran</i>	1210
29.19	Nocardiosis <i>Subhasish Bhattacharyya</i>	1212
29.20	Actinomycosis <i>Subhasish Bhattacharyya</i>	1214
29.21	<i>Helicobacter pylori</i> <i>John Matthai, Sarah Paul</i>	1215
29.22	Anaerobic Infections <i>Rekha Harish, Anuj Bhatti</i>	1217

Section 30: MYCOBACTERIAL INFECTIONS

Section Editor Soumya Swaminathan

30.1	Antitubercular Drugs <i>Geetha Ramachandran</i>	1220
30.2	Tuberculosis <i>Soumya Swaminathan, N Pooranagangadevi, Ben J Marais</i>	1225
30.3	Atypical Mycobacterial Infections <i>C Padmapriyadarsini, Soumya Swaminathan</i>	1235
30.4	Leprosy <i>Rajeshwar Dayal, Manoj Kumar Singh</i>	1239

Section 31: VIRAL DISEASES

Section Editors Ashok Kumar Dutta, Piyush Gupta

31.1	Epidemiology of Viral Infections <i>VG Ramachandran, Piyush Gupta</i>	1243
31.2	Poliomyelitis <i>Ashok Kumar Dutta</i>	1245
31.3	Measles <i>Shilpa Khanna Arora, Piyush Gupta</i>	1248
31.4	Mumps <i>Shilpa Khanna Arora, Piyush Gupta</i>	1252
31.5	Rubella <i>Pooja Dewan, Piyush Gupta</i>	1255
31.6	Varicella <i>Piyush Gupta, Aashima Dabas</i>	1259
31.7	Parvovirus Infections <i>Jagdish Chandra, Anu Maheshwari</i>	1263
31.8	Roseola Infections <i>Swati Singhal</i>	1268
31.9	Viral Hepatitis <i>Amit Goel, Chhavi Nanda</i>	1270
31.10	Rabies <i>Jaydeep Choudhury</i>	1275

31.11	Japanese Encephalitis <i>Rashmi Kumar, Piyush Tripathi</i>	1278	32.13	Filariasis <i>Ajay Gaur</i>	1368
31.12	Infectious Mononucleosis <i>Rashmi Ranjan Das</i>	1282	32.14	Intestinal, Liver and Lung Flukes <i>Vikas Jain</i>	1372
31.13	Enteroviral Infections <i>Annapurna Sudarsanam</i>	1287	32.15	Tapeworm Diseases <i>Ruchi Rai</i>	1376
31.14	Herpes Simplex Infections <i>Niranjan Mohanty, Pradeep S</i>	1292	32.16	Hydatid Disease: Echinococcosis <i>SK Gupta</i>	1380
31.15	Influenza <i>Sonal Kansra, Alison Scott</i>	1296	32.17	Schistosomiasis <i>Ritabrata Kundu, Devdeep Mukherjee</i>	1384
31.16	Dengue <i>Piyush Gupta, Aashima Dabas</i>	1299	Section 33: FUNGAL INFECTIONS		
31.17	Chikungunya Fever <i>Rajniti Prasad</i>	1307	Section Editor Piyush Gupta		
31.18	Viral Hemorrhagic Fevers <i>Nigam Prakash Narain, Priya Verma</i>	1310	33.1	Fungi <i>VG Ramachandran, Piyush Gupta</i>	1386
31.19	HIV and Acquired Immunodeficiency Syndrome <i>Milind S Tullu, Chhaya Divecha</i>	1313	33.2	Antifungal Therapy <i>Arunaloke Chakrabarti, Prashant Sood</i>	1387
Section 32: PARASITIC INFECTIONS AND INFESTATIONS			33.3	Candidiasis <i>Khaya Ghosh Uttam</i>	1392
Section Editors Ritabrata Kundu, Piyush Gupta			33.4	Aspergillosis <i>Kana Ram Jat</i>	1396
32.1	Epidemiology of Parasitic Infections <i>Piyush Gupta, VG Ramachandran</i>	1328	33.5	Cryptococcosis <i>Ankit Parakh</i>	1399
32.2	Malaria <i>Ritabrata Kundu</i>	1331	33.6	Coccidioidomycosis <i>James Homans, Yee Aye</i>	1402
32.3	Leishmaniasis <i>Shyam Sundar, Jaya Chakravarty</i>	1337	33.7	Blastomycosis <i>G Raghurama Rao</i>	1407
32.4	Amebiasis <i>Piyush Gupta, Aashima Dabas</i>	1343	33.8	Histoplasmosis <i>S Nivedhana, S Balasubramanian</i>	1409
32.5	Giardiasis <i>Aashima Dabas, Piyush Gupta</i>	1347	33.9	<i>Pneumocystis jirovecii</i> (previously classified as <i>P. carinii</i>) <i>Ira Shah, Khushnuma Mullanfiroze</i>	1412
32.6	Cryptosporidiosis <i>Aashima Dabas, Piyush Gupta</i>	1350	Section 34: RICKETTSIAL AND OTHER INFECTIONS		
32.7	Ascariasis <i>Sutapa Ganguly</i>	1352	Section Editors S Balasubramanian, Piyush Gupta		
32.8	Hookworm Infestation <i>Maitreyi Basu, Sutapa Ganguly</i>	1355	34.1	Epidemiology, Classification, and Approach to Diagnosis of Rickettsial Infections <i>Narendra Rathi</i>	1415
32.9	Trichuriasis <i>Sutapa Ganguly</i>	1358	34.2	Spotted Fevers <i>Atul A Kulkarni</i>	1418
32.10	Enterobiasis <i>Dhrubojyoti Mridha, Sutapa Ganguly</i>	1360	34.3	Scrub Typhus <i>Veena R Parmar</i>	1422
32.11	Strongyloidiasis <i>Ravi Ambey, Tripty Naik</i>	1362	34.4	Epidemic Typhus <i>Sunil Vaidya, Atul A Kulkarni</i>	1424
32.12	Trichinosis <i>Akash Bang, Puja Hingorani</i>	1365	34.5	Murine Typhus (Endemic Typhus) <i>Govind Benakatti, LH Bidari</i>	1426

34.6	<i>Mycoplasma</i> Infections <i>Tanu Singhal</i>	1428	35.19	Abdominal Tuberculosis <i>Yogesh Waikar</i>	1496
34.7	Chlamydial Infections <i>Sulochana Putali Bai</i>	1430	35.20	Ascites <i>Malathi Sathiyasekeran, R Ganesh</i>	1498

PART VIII: Systemic Disorders

Section 35: GASTROINTESTINAL DISORDERS

Section Editors *A Riyaz, John Matthai*

35.1	Anatomy and Physiology <i>S Arivu Selvan</i>	1432	35.23	Appendicitis <i>Prakash Agarwal</i>	1506
35.2	Common Symptoms of Gastrointestinal Diseases <i>Sarah Paul, John Matthai</i>	1437	35.24	Testicular Torsion <i>Prakash Agarwal</i>	1508
35.3	Cleft Lip and Cleft Palate <i>VS Akbar Sherif, Sayed Mohammed Akbar</i>	1439	35.25	Inguinal Hernia <i>Prakash Agarwal</i>	1510
35.4	Dental Caries <i>Madhu S</i>	1442	Section 36: DIARRHEAL ILLNESSES		
35.5	Recurrent Parotitis <i>Prakash Agarwal</i>	1445	Section Editor <i>AK Patwari</i>		
35.6	Vomiting <i>Sumathi Bavanandam</i>	1447	36.1	Acute Watery Diarrhea <i>AK Patwari</i>	1511
35.7	Infantile Hypertrophic Pyloric Stenosis <i>Ketan Parikh</i>	1451	36.2	Dysentery <i>AKM Iqbal Kabir, Lazina Sharmin</i>	1519
35.8	Gastroesophageal Reflux <i>Elsie Jazmin Foglio, Dinesh S Pashankar</i>	1453	36.3	Cholera <i>Piyush Gupta, Rashi Singhal</i>	1523
35.9	Umbilical Hernia <i>Prakash Agarwal</i>	1457	36.4	Persistent Diarrhea <i>Shinjini Bhatnagar, Aashima Dabas, Dheeraj Shah</i>	1527
35.10	Constipation <i>Praveen Kumar, Preeti Singh</i>	1459	36.5	Chronic Diarrhea <i>BR Thapa, Srikanth KP, Babu Lal Meena</i>	1533
35.11	Hirschsprung Disease <i>Ketan Parikh</i>	1464	36.6	Antibiotic Associated Diarrhea <i>Seema Alam, Vikrant Sood</i>	1551
35.12	Chronic Abdominal Pain <i>B Bhaskar Raju, Sumathi Bavanandam</i>	1466	Section 37: HEPATOBILIARY DISEASES		
35.13	Acid Peptic Disease <i>R Bhanu Vikraman Pillai</i>	1470	Section Editor <i>Surender Kumar Yachha</i>		
35.14	Pancreatitis <i>A Riyaz, Geeta M Govindaraj</i>	1473	37.1	Applied Anatomy and Physiology of Liver and Biliary Tract <i>Vishnu Biradar</i>	1555
35.15	Practical Approach to Malabsorption <i>VS Sankaranarayanan</i>	1478	37.2	Liver Function Tests <i>Neelam Mohan, Sakshi Karkra</i>	1558
35.16	Specific Malabsorption Syndromes <i>Srinivas S</i>	1481	37.3	Neonatal Cholestasis <i>Surender Kumar Yachha, Moinak Sen Sarma</i>	1563
35.17	Inflammatory Bowel Disease <i>Rishi Bolia, Anshu Srivastava</i>	1484	37.4	Portal Hypertension <i>Surender Kumar Yachha, Moinak Sen Sarma</i>	1571
35.18	Celiac Disease <i>Lalit Bharadia</i>	1491	37.5	Gastrointestinal Bleeding <i>Nishant Wadhwa</i>	1586
			37.6	Liver Abscess <i>Upender Shava, Anshu Srivastava</i>	1593
			37.7	Acute Hepatitis <i>Barath Jagadisan</i>	1598

37.8	Chronic Liver Disease <i>Seema Alam, Rajeev Khanna</i>	1602	38.18	Other Clotting Factor Deficiencies <i>Sunil Gomber, Archana Kashyap</i>	1731
37.9	Hepatic Encephalopathy <i>Moinak Sen Sarma, Surender Kumar Yachha</i>	1616	38.19	Thrombocytopenia <i>Amita Trehan</i>	1735
37.10	Acute Liver Failure <i>Anupam Sibal, Vidyut Bhatia, Akshay Kapoor</i>	1624	38.20	Immune Thrombocytopenic Purpura <i>Jagdish Chandra, Dinesh Yadav</i>	1741
37.11	Liver Tumors <i>Karthick Sundaram, Naresh P Shanmugam</i>	1627	38.21	Platelet Function Defects <i>Neelam Varma</i>	1749
			38.22	Thrombotic Disorders <i>Sidharth Totadri, Deepak Bansal, RK Marwaha</i>	1753
Section 38: DISORDERS OF HEMATOPOIETIC SYSTEM			38.23	Disseminated Intravascular Coagulation <i>VK Khanna, Tarangini D, Anupam Sachdeva</i>	1762
Section Editor <i>VP Choudhry</i>			38.24	Blood Component Therapy <i>Anupam Verma, Hemlata, Nabajyoti Choudhury</i>	1767
38.1	The Hematopoietic System <i>Praveen C Sobti, Shruti Kakkar</i>	1632	38.25	Stem Cell Transplantation <i>Mammen Chandu</i>	1771

PART VII Infectious Diseases

Section 27 BASIC CONCEPTS

Section Editors Jaydeep Choudhury, Piyush Gupta

Chapter 27.1

Epidemiology of Infectious Diseases

VG Ramachandran, Piyush Gupta

DEFINITIONS

Asepsis Combination of efforts directed at preventing entry of microorganisms into any area of body where they are likely to, cause infection.

Carrier A person or animal that has a specific infectious agent in the absence of a clinical disease. A carrier serves as a potential source for further transmission in the community. *Temporary carrier* state lasts for less than 6 months. *Chronic carrier* state is prolonged and may last lifelong.

Case A person who is identified as having a particular characteristic, such as a disease, behavior or condition. An epidemiological definition of a case is not necessarily the same as the clinical definition. Cases may be categorized as possible, probable and definite, depending on how well a set of specific criteria is satisfied.

Chemoprophylaxis Administration of drugs to prevent infection from (i) occurring in the first place; or (ii) progressing into disease.

Contact Exposure to the source of an infection. Transmission due to direct contact may occur when s in or mucous membranes touch, as in body contact, kissing and sexual intercourse.

Contagious Transmitted by contact or close proximity.

Control Disease control programs aim to lower the incidence of new cases, or reduce the proportion of severe cases through treatment to an acceptably low level, so that the disease is no longer considered a major public health hazard.

Decontamination Process that makes objects safer to be handled; it may reduce but does not eliminate microorganisms on the object.

Disinfection Process that eliminates most but not all disease-causing microorganisms from inanimate objects.

Endemic A disease or infectious agent persistent in a given population; also referred to as a disease with a constant incidence of new cases in the area.

Epidemic It is defined as the occurrence, in a community or area, of cases of a disease clearly in excess to what has been expected. In other words, there is an increase in the incidence of the disease above the endemic level. This is a relative term and would differ from one setting to another (for example, 20 cases of pulmonary

tuberculosis in a particular geographic region in a developed country, where tuberculosis is rare, would constitute an epidemic, whereas a similar situation in India would not be abnormal).

Eradication The extermination of an infectious agent, halting transmission of the infection altogether from a given area.

Hyperendemic A disease that is constantly present at a high incidence or prevalence, and affect all age groups.

Incubation period Time interval between invasion of a susceptible host by an infectious agent and the appearance of the first symptom or sign of the disease. For each organism, there is a characteristic range within which, infecting dose, portal of entry as well as host factors like age and immunosuppression give rise to individual variability.

Infection The condition wherein an infectious agent lives and multiplies in the body of the host. Multiplication of the bacteria which are part of the normal flora of the gastrointestinal tract, respiratory mucosa, etc., is generally not considered an infection. On the other hand, multiplication of certain pathogenic bacteria (e.g., *Salmonellae*) is considered an infection even if the person is asymptomatic.

Infection, Iatrogenic Physician-induced infection resulting from some form of intervention, e.g., drug therapy, diagnostic procedures, etc.

Infection, Cross When a new infection from a patient or a healthy carrier establishes itself in an already diseased person.

Infection, Primary It is the very first or the initial infection caused by an infecting organism. Subsequent infection by the same organism is called re-infection. When host resistance is diminished by a pre-existing infectious disease, a new microorganism sets up an infection, which is called secondary infection.

Infection, Nosocomial Cross infection acquired in a hospital. Now known as hospital associated infection (HAI).

Infection, Airborne A disease that is caused by an infectious agent capable of being transmitted by particles or droplets suspended in the air, e.g., measles and whooping cough.

Infection, Atypical Infection where the typical or characteristic clinical symptoms and signs of a particular disease are lacking.

Infection, Endogenous Infection derived from the person's own microflora.

Infection, Exogenous Infection derived from extraneous source, e.g., another human being, environmental source or animal (zoonoses).

Infection, Inapparent or Subclinical An infection that does not cause any detectable clinical signs and symptoms.

Infection, Latent Following an infection, some pathogens may remain in dormant form in host tissues and proliferate only when host resistance is lowered, producing clinical disease.

Invasion The process by which bacteria, animal parasites, fungi and viruses enter the host-cells and spread in the body.

Isolation Separation, for the period of communicability, of infected persons or animals from others in such places and under such conditions as to prevent or limit the direct or indirect transmission of the infectious agent from those infected to those who are susceptible or who may spread the agent to others.

Non-pathogen A microorganism that does not cause disease, but may be a part of the normal flora.

Notifiable disease A disease that by statutory requirements must be reported to the public health authorities.

Outbreak Two or more related cases in infections, suggesting the possibility of a common source or transmission between cases.

Pandemic A worldwide epidemic or an epidemic occurring over a very wide area.

Pathogen A microorganism capable of causing disease.

Pathogen, Opportunistic A microbe capable of causing disease only when the host resistance is compromised.

Pathogenesis Mechanism by which a pathogenic agent produces disease.

Pathogenicity The ability of an infectious agent to cause disease.

Period of communicability The period during which the infectious agent may be passed from a case to other persons in the population, or from an animal to man or vice versa. In some infections, asymptomatic, temporary or chronic carriers may also pass an infection to susceptible persons (e.g., typhoid bacilli).

Reservoir The natural habitat of an infectious agent, where the infectious agent may survive or multiply. It may be human, animal or the inanimate environment such as soil.

Sporadic A disease or event that occurs infrequently and irregularly. Resultant cases are not related to other cases or infection.

Sterilization Elimination of all microorganisms from an object including spores and vegetative forms.

Transmission The spread of an infectious agent, either through the environment or from person to person. The main mechanisms of transmission are direct contact, placental, fomite-borne, vector-borne and airborne.

Vehicle The term is used for inanimate sources of infection, e.g., food, water or fomites.

Zoonosis An infectious disease that is transmitted naturally from vertebrate animals to human beings.

SPREAD OF INFECTION

A communicable disease develops due to the transmission of an infectious agent or its toxic products from an infected person, animal or reservoir to a susceptible host—either directly or indirectly through an intermediate plant or animal host, vector or the inanimate environment (**Box 1**).

Communicable diseases may occur sporadically or in the form of an outbreak. Their incidence is directly related to the general well-being of the society. In developed nations, many of the communicable diseases are rarely seen. However, sexually transmitted diseases and acute respiratory infections are ubiquitous in their occurrence.

Etiological Agents

Bacteria

They cause diseases by (a) invading the tissues or the bloodstream and multiplying in a part of body, which is normally devoid of bacteria; (b) producing a toxin, which might act locally, or at a body site which is far from the site of bacterial multiplication and toxin production; or (c) causing a hypersensitivity reaction, e.g., group A beta hemolytic streptococci causing rheumatic fever or acute glomerulonephritis.

BOX 1 Steps in the spread of an infectious disease

The development or spread of an infectious disease presupposes the presence of the following:

1. An *etiological agent* responsible for the disease should be present
2. There should be a *reservoir* of the etiological agent
3. The infecting agent should be able to escape from the reservoir of infection, through the *portal of exit*
4. There should be a *possible portal of entry* to transmit the agent from the reservoir to the new host
5. The agent should be *able to invade* the tissues of the new host
6. The host receiving the infecting agent should be *susceptible* to the infection.

Virus

These are very small organisms and contain protein encapsulated genetic material which could either be DNA or RNA. The virus attaches to a cell in the human body and then releases its genetic material inside the cell. This genetic material of the virus subjugates the host cell and diverts its normal function in a variety of ways. The host cell can now only produce more and more of virus particles, which invade new cells.

Fungi

These are cellular structures of the plant kingdom. These exist either as yeast (which reproduces asexually by budding) or mycelia (with long branching filaments).

Protozoa

They are unicellular parasites such as malarial parasite and amoebae.

Metazoa

They are multicellular parasites, such as tapeworm, hookworm and blood or liver flukes.

Rickettsia

These are small organisms related to bacteria structurally, but multiply intracellularly like viruses, causing diseases like typhus fever.

Reservoir of Infection

Generally, disease causing organisms do not remain viable outside the living body for a long time. They need to enter the body or tissues of humans, animals, insects or plants which serve as reservoirs of infection. Of these, the human reservoir is the most significant in a clinical situation. Organisms capable of causing disease in man are derived from human, animal or inanimate sources. The relative importance of the three sources depends primarily on the fact that different organisms are adapted to different natural habitats.

Human Sources

Individual's own organisms A normal human infant is free of microbes at birth, but rapidly acquires a complex bacterial flora

from other human beings. This flora, though harmless under ordinary circumstances, may produce diseases in favorable circumstances. *Bacteroides*, *E. coli* and other organisms are harmless commensals of the gut but can cause peritonitis if the bowel wall is mechanically damaged; *E. coli* is also the most common cause of urinary tract infection. *Haemophilus influenzae*, *Streptococcus pneumoniae* and *Streptococcus viridans* live harmlessly in the upper respiratory tract, but can cause bronchitis, bronchopneumonia, sinusitis and otitis media, etc., if the mucous membrane is damaged by moisture, common cold or influenza. Injuries and operation wounds also offer abundant scope for endogenous bacterial infection.

Patient incubating a disease During the incubation period of an infectious disease, the prospective patient may remain apparently healthy but highly infectious. Patients of illnesses like chickenpox and hepatitis A may transmit the infection to other persons during the incubation period, shortly before they become symptomatic. In hepatitis A, the feces are infectious for about 2 weeks prior to the onset of jaundice. In hepatitis B, the blood is infectious for more than a month before the clinical symptoms set in. In rubella, mumps and poliomyelitis, the upper respiratory tract is a source of infection for a few days before the onset of symptoms. Patients who are infectious while incubating a disease are referred to as incubatory carriers.

Patient with overt disease A patient suffering from an acute or chronic infectious disease frequently throws out a large number of the causative organisms into the environment through various body fluids: feces, urine, droplets or discharges from the mouth, nose, ears, eyes and discharges of pus from internal organs, wounds, ulcers, sores and other skin lesions. In acute infections, the organisms are secreted for a short while only, while in certain chronic conditions like tuberculosis, the organism may continue to get excreted for a longer duration.

All infected individuals are not necessarily a source of infection for others—the pathogen may get lodged in a deep-seated organ, such as the meninges from which exit to another host is impossible (e.g., neurocysticercosis, toxoplasmosis). On the other hand, the pathogen may be so virulent as to kill the host and annihilate itself in the process. Patients suffering from grave life-threatening, infectious illnesses have a poor prognosis but they often do not pose significant hazard to the community—since such patients are usually confined to bed or isolated, and do not commonly come in contact with other unaffected persons in the community, except with their own family members or immediate attendants and neighbors. These patients are often diagnosed early and are treated appropriately to eliminate the reservoir of infection and make them non-infective.

Convalescent carriers In many infectious diseases, the causative organisms are not eliminated even after the clinical recovery has taken place. The organisms may persist in the throat following diphtheria or streptococcal sore throat, and may continue to be excreted in the feces after recovery in typhoid, dysentery or poliomyelitis. Such individuals are known as convalescent carriers or convalescent excretors. The carrier state is usually temporary but may persist longer in around 10% cases. Those who shed the organisms for less than a year are known as temporary carriers. Chronic carriers keep on excreting the organisms for more than a year following an illness, e.g., typhoid fever.

Contact carriers Persons in contact with a patient suffering from an infectious disease may acquire the organism and harbor it without suffering from any apparent disease; patients who have recently recovered from an infection may continue to discharge the organisms for several weeks during convalescence. Such individuals are known as contact carriers and asymptomatic excretors, respectively. Contact carrier state may be temporary

or prolonged. The interaction between the host and the parasite may result in a very mild form of the disease, or a relationship, which can best be regarded as commensalism. In an outbreak of poliomyelitis, cases of the overt disease are greatly outnumbered by cases of inapparent or subclinical infection, which are nevertheless infectious. A high proportion of healthy hospital workers carry *Staphylococcus aureus* on their skin and nose, and are undesirably the most important source of hospital-borne infection. Other diseases, where contact carriers are common, include diphtheria, streptococcal sore throat, meningococcal meningitis, dysentery and hepatitis B. Contact carriers constitute a special hazard for they have a disease that is subclinical.

Animal Sources

Infectious diseases, which are transmitted naturally between vertebrate animals and men are called *zoonoses*. These may be classified on the basis of their etiology, reservoir or the life cycle of the infecting organism (**Box 2**). Cows may excrete *M. tuberculosis* or *Brucella abortus* in their milk and *Campylobacter jejuni* in feces. The viruses of cowpox and milker's node may be present in lesions on the udder. They are often infected with ringworm fungi and sometimes with the beef tapeworm, *Taenia saginata*. Goats in the Mediterranean region may excrete brucella in their milk and may be infected with *Bacillus anthracis*. Sheep are the natural source of the liver fluke, *Fasciola hepatica*. Horses excrete *Clostridium*

BOX 2 Classification of zoonoses with respect to etiology, reservoir or life cycle of the infecting organism

With respect to etiology

Bacterial zoonoses	Brucellosis, anthrax, plague, salmonellosis.
Viral zoonoses	Rabies, Japanese encephalitis and other arboviral infections.
Parasitic zoonoses	Toxoplasmosis (protozoan), hydatid disease (helminthic), myiasis (ectoparasitic).
Fungal zoonoses	Histoplasmosis, cryptococcosis, superficial dermatophytic infections (some).
Rickettsial zoonoses	Murine typhus, tick fever, Q fever.

With respect to reservoir

Anthropozoonoses	Infections transmitted from the lower vertebrate animals to man.
Zooanthroponoses	Infection primarily of human origin, transmitted from man to lower vertebrate animals.
Amphixenoses	Infection maintained in man and lower vertebrate animals and may be transmitted in either direction.

With respect to life cycle of the infecting organism

Direct zoonoses	Infection transmitted from the infected vertebrate host (animal) to a susceptible vertebrate host (e.g., man), either by direct contact, contact with fomites or by mechanical transmission through a vector. During transmission, the agent undergoes no developmental or propagative changes (e.g., trichinosis).
Cyclozoonoses	Infection requires more than one vertebrate host species in order to complete the life cycle of the agent. No invertebrate hosts are required (e.g., echinococcosis, taeniasis).
Metazoonoses	Infection is transmitted biologically by the invertebrate vectors, e.g., mosquito. The parasite characteristically develops or multiplies in the invertebrate. There is a mandatory pre-patent period (extrinsic incubation period) before the agent can be transmitted back to a susceptible vertebrate host (e.g., kala-azar and dengue fever).
Saprozoonoses	Infection is transmitted from the inanimate developmental sites or reservoirs such as soil, plant and food to the susceptible vertebrate hosts (e.g., larva migrans).

tetani in their feces and are often infected with ringworm fungi. Dogs transmit rabies virus by their bite, leptospira in their urine, ringworm fungi by contact with their skin and hair, and the ova of the hydatid-worm *Echinococcus granulosus* and the roundworm *Toxocara canis* through their feces.

Cats can be a source of ringworm fungi. *Toxoplasma gondii* may be transmitted by the feces of the cat containing its oocyst. Monkeys are the natural hosts of yellow fever virus and also dengue fever virus in some areas. These diseases are conveyed to man by mosquitoes. Pigs may be infected with *Brucella suis*, *Salmonellae*, *Balantidium coli*, the pork tapeworm *Taenia solium* and the nematode *Trichinella spiralis*. Rats may be infected with *Yersinia pestis* and transmitted to man by fleas, resulting in plague. Leptospira may be excreted in urine and enter the human body through cuts and abrasions. Rat bite fever occurs due to *Spirillum minus* or *Streptobacillus*. Rats commonly excrete *Salmonellae* in their feces. They are the natural host of the virus of lymphocytic choriomeningitis. Chickens, turkeys and ducks can excrete *Salmonellae* in their feces. These organisms frequently contaminate the meat. Duck eggs are liable to contain *Salmonellae*. Parrots, pigeons and other birds may excrete the organisms of psittacosis (*Chlamydia psittaci*) and ornithosis in their feces. Tortoises, terrapins, turtles and lizards may excrete *Salmonellae*. Fish may be infected with *Vibrio parahaemolyticus* and the fish tapeworm, *Diphyllobothrium latum*. Various domestic and wild animals are the natural hosts of *Listeria monocytogenes*, *Yersinia enterocolitica* and *Pasteurella haemolytica*. Wild animals are also hosts for rickettsiae causing various types of typhus fever, arboviruses causing encephalitis and febrile illness and various protozoa, such as trypanosomes. These diseases are transmitted by arthropod vectors.

Inanimate Sources

Pseudomonas, *Proteus* and many species of *Clostridium* are capable of a free-living existence in the soil where they obtain nourishment from decaying animals and vegetable matter. They are also common intestinal commensals of man and animals and may be returned to the soil in their feces. These organisms show little tendency to produce disease spontaneously. *Pseudomonas* and *Proteus* may infect burns, wounds and urinary tract; *Clostridia* may produce tetanus and gas gangrene under anaerobic conditions, such as a deep wound contaminated with soil.

Transmission to Host

The infecting organisms may be transferred from the reservoir to the host either *directly* or *indirectly*. **Box 3** depicts the common routes of exit of an agent from the reservoir and entry into the host.

BOX 3 Routes of exit and entry of microorganisms

A. Routes of exit from the reservoir

1. *Respiratory tract* during processes of normal breathing, speaking, sneezing, coughing and through sputum
2. *Gastrointestinal tract* in the feces
3. *Urinary tract* in the urine
4. *Skin* through superficial lesions, such as in impetigo, chickenpox and syphilis
5. *Genital tract*, such as cytomegalovirus, rubella, toxoplasmosis, *Chlamydia*, HIV and semen as in AIDS

B. Routes of entry into a new host

1. *Inhalation*: Airborne inhalation and infection through the respiratory tract
2. *Ingestion*: Food-borne ingestion and infection through the alimentary tract
3. *Inoculation*: Inoculation through skin and mucous membranes
4. *Transplacental*: From mother to fetus.

Direct Transmission

The etiologic agent is transmitted directly into the host through: (i) either from skin to skin (impetigo and sexually transmitted diseases, such as hepatitis B, AIDS, herpes and syphilis); or (ii) by droplet spread through coughing, talking and sneezing as in measles, chickenpox, tuberculosis and even leprosy.

Transmission can occur only in a susceptible host, in an overcrowded place within 1–2 m of the patient, who is transmitting the agent. Droplets of mumps and rhinovirus that fall on the ground are not able to infect the host, but mycobacteriae of tuberculosis and leprosy are potentially viable for some time and can become a part of the household dust and thus contaminate the air.

Indirect Transmission

The etiologic agent may be transmitted to a host who may be at a distant site, through the following mechanisms:

Vectors Vectors include ticks, mites and insects, such as fleas, flies, lice and mosquitoes. They might transmit the infection mechanically by carrying the organisms on their feet or wings. Infecting agent may actually grow in the body of the vector, e.g., malarial parasites in mosquito.

Vehicles These include air, dust, water, milk, food, clothing, bedding, medical, surgical and dental instruments, appliances, dressings, books and toys contaminated by a patient and are referred to as fomites.

Modes of Transmission

Airborne Transmission

During breathing, moist surfaces of nasopharynx and lower respiratory tract trap the organisms in the contaminated air. This is the usual mechanism of transmission of streptococcal sore throat, diphtheria, meningococcal meningitis, whooping cough, pulmonary tuberculosis, plague, measles, influenza and the common cold. The organisms may reach the recipient by *direct transfer*, *droplet infection* or *through dust*.

Droplet infection A small number of organisms escape into the air from the nose or mouth during normal expiration or in quiet conversation. Coughing and sneezing and nose blowing result in the release of a vast number of organisms into the air from the mouth and the nose respectively. Particles from the respiratory tract are released in the form of droplets—a vigorous cough may liberate 5,000 and a vigorous sneeze, as many as a million droplets. Most droplet nuclei are sterile and even in patients infected with severe and contagious infections, such as with *Mycobacterium tuberculosis*, *Streptococcus pyogenes* and *Corynebacterium diphtheriae*, only a minute proportion of droplets contain the pathogen. Some of these droplets have a diameter of 100 nm or more but most of them are less than 100 nm. The smaller droplets evaporate almost instantaneously and remain suspended in the air for many hours as droplet nuclei before falling to the ground. Larger droplets have an extremely short trajectory and fall rapidly towards the ground and contaminate whatever is immediately in front and below the patient. Even in vigorous coughing or sneezing, these droplets do not travel for more than 0.5–0.75 m in a horizontal direction. Larger droplets contain more organisms but their short trajectory limits their ability to cause direct infection. A cough or sneeze aimed directly at the face of the victim is a certain way of transferring infection.

Both bacterial and viral diseases can be spread by droplet infection, particularly the latter. Droplet infection is of specific importance in the spread of bacteria such as *Neisseria meningitidis* and *Bordetella pertussis* which are rapidly killed by drying. In other diseases, the expulsion of droplets may be a more important source of contaminating the environment.

Dust-borne infection An infected person firstly contaminates himself and his environment by releasing droplets or by direct outflow of secretions. Later on, the organisms in droplets or secretions are conveyed to the recipient in the form of dust. People who carry *S. aureus* and *Streptococcus pyogenes* in their nose or throat are also likely to have them on their skin, hands, face, clothing, handkerchief, pockets and on objects with which they are in close contact, e.g., bedding, handbags, books, pens, etc. The infected secretions dry on whatever they happen to contaminate. Many organisms will survive for days or weeks even under these conditions if they are shielded from direct sunlight (e.g., *M. tuberculosis*, *Streptococcus pyogenes*, *S. aureus* and *Corynebacterium diphtheriae*). Large number of dust particles is liberated from the skin, clothing and fomites during normal body movements, and at the time of other household processes, such as bed making, sweeping and dusting. Inhalation of such infected dust particles is an important mode of infection for many bacterial diseases of the respiratory tract.

Gastrointestinal Transmission

Infection through gastrointestinal tract may be acquired by directly ingesting the organisms themselves (e.g., *Salmonellae*, *Shigellae*, *E. coli*, *Vibrio cholerae*, *Campylobacter jejuni*, *Yersinia enterocolitica*, rotavirus, cysts of the protozoa *Entamoeba histolytica* and *Giardia lamblia* and ova of various intestinal helminthes, such as roundworms and tapeworms) or their pre-formed toxins (e.g., toxins of *S. aureus* and *Vibrio cholerae*). *Clostridium perfringens* forms toxin in the gut thereby causing disease. Certain organisms enter by the intestinal tract but cause their main symptoms elsewhere (e.g., *Brucella*, hepatitis A, polio, coxsackie and echoviruses and *Toxoplasma gondii*).

The feces of a case or carrier is by far the most important source of the intestinal pathogen. Occasionally, the organisms may also be excreted in the urine, e.g., in enteric fever. Milk and water also constitute important modes of infection through ingestion.

Direct contamination Objects may be contaminated by feces or by the hands. When a patient has diarrhea, contamination is more likely by touching the patient or fomites contaminated with fecal material. Subsequently, the recipient may transfer infection to his mouth by means of fingers, eating utensils, feeding bottles and other objects. *Shigella* dysentery and *E. coli* diarrhea are frequently spread in this manner.

Food-borne infections These may be caused by a carrier engaged in handling and preparing food, or by the contaminated food itself. Affected individual may thus present either as a case of food poisoning or infective diarrhea. Milk offers an excellent medium for multiplication of certain bacteria unless it is refrigerated. Pathogens in the milk may be derived from the cows, (e.g., *M. bovis*, *Brucella abortus*, *Coxiella burnetii* and *Campylobacter jejuni*) or get introduced by dairy workers, or by contaminated water or equipment (e.g., *Streptococcus pyogenes*, *C. diphtheriae*, *Salmonellae*, and *Shigellae*). Certain other organisms turn the milk sour but are harmless, e.g., *E. coli* and lactobacilli. All the pathogens are killed by pasteurization.

Food poisoning Consumption of contaminated food at community gatherings frequently results in large outbreaks of diarrhea and vomiting. Most food poisonings are bacterial in origin—staphylococcal food poisoning is due to the consumption of preformed enterotoxins, while *Clostridium perfringens* food poisoning is caused by ingesting a large dose of the organisms which then release the toxins in the gut. Such type of poisoning is not infective by contact. The onset is usually explosive and majority of the individuals are influenced within a few hours after

consumption of the affected food (e.g., 2–6 hours with *S. aureus* and 6–12 hours with *Clostridium perfringens*). The symptoms may be severe but rarely last for more than 24 hours. Prostration is common and pyrexia does not occur. Vomiting is unusual in *Clostridium perfringens* food poisoning.

Water-borne infections These occur by seepage from a privy cesspit, or sewer into a well or water supply, or by direct pollution of water by a carrier; water may itself spread infection or contaminate food. Water-borne infections have been responsible for many major epidemics of cholera and typhoid in the past. Improvement in sewage disposal, water purification and piped supply are the basic requirements to contain water-borne infections.

Transmission through Inoculation

Through intact skin The venereal diseases, syphilis and gonorrhea are spread by contact of genital mucous membranes and very rarely by other means. Close physical contact is important in the spread of: (a) skin infections, such as impetigo, boils, warts, herpes simplex and ringworm; (b) diseases which affect the skin, such as leprosy, yaws, and the rashes of secondary syphilis; and (c) infection of the conjunctivae caused by *Chlamydia trachomatis*.

Through a break in the skin Wound infection follows a break in the continuity of skin or mucous membranes. This may happen following accidental injuries, burns, surgical procedures and childbirth. *S. aureus* is one of the most common pathogenic organisms responsible for wound infection. Patients with staphylococcal infections are likely to contaminate their immediate environment and other individuals in the community unless elaborate precautions are taken. Transfer of infection to clean wounds from other patients with septic lesions is more commonly the result of airborne contamination rather than by direct inoculation—*Clostridium perfringens* and *Clostridium tetani* are introduced at the time the wound is inflicted. The same applies to rabies virus, which is acquired from the bite of a rabid animal, usually a dog. *E. coli* and bacteroid infections may follow abdominal surgery due to lapses in hygienic precautions.

Blood-borne Hepatitis B virus is present in the blood of certain individuals and the most important mechanisms by which it is transmitted to another human being is by injection—e.g., by using needles and syringes contaminated with traces of human blood, and improperly sterilized equipment of dentists, chiropodists, acupuncturists, tattooists, barbers, ear-piercers, etc., and blood transfusion. Hepatitis C virus, HIV, human T-lymphotropic virus (HTLV) and cytomegalovirus may also get transmitted by transfusion of improperly screened blood.

Vector-borne Arthropod vectors are important in the transmission of diseases caused by arboviruses, protozoa, some helminths, rickettsiae and a few bacteria (**Box 4**). Insects become infected when they bite a host whose blood contains the particular organisms. They do not behave as passive carriers, as do flies in transmitting *Salmonellae* and *Shigellae* from feces to food, but act as a host in which the organisms can multiply. There is normally

BOX 4 Vectors and diseases

Mosquitoes	Malaria, yellow fever, dengue, Japanese encephalitis, filariasis
Sandflies	Sandfly fever, leishmaniasis
Tse-tse flies	Trypanosomiasis
Fleas	Bubonic plague, murine typhus
Lice	Epidemic typhus, trench fever
Ticks	Kyasanur forest disease, Rocky mountain spotted fever
Mites	Scrub typhus, Rickettsial pox.

an interval of several days before the insects are capable of transmitting infection (extrinsic incubation period).

Lower animals are the natural hosts of most diseases transmitted to man by biting insects. In some, however, man is the primary host and there is no animal reservoir of infection; for example, epidemic typhus, sandfly fever and malaria are transmitted by insect from man to man.

Transplantation Transplant material, such as kidneys, bone marrow and corneal grafts may convey infection from one person to another. The infecting agent is most commonly a virus that has been lying dormant in the tissues of the donor. In the recipient, the virus becomes reactivated because of the low host resistance brought about by immunosuppressive therapy. Cytomegalovirus is the most frequent offender. Corneal graft and growth hormone therapy have on occasion transmitted serious prion disease, Creutzfeldt-Jakob disease.

Transplacental Transmission

Placenta is an effective barrier to infection. Certain organisms including the bacteria (*Treponema pallidum*, *Listeria*), viruses (rubella, cytomegalovirus, hepatitis B virus) and protozoa (toxoplasma) may, however, readily cross the placenta and cause fetal afflictions. Rubella virus infection in the first trimester of pregnancy frequently produces congenital abnormalities in the fetus.

Multiple routes

Certain organisms can infect a host through several different portals. *M. tuberculosis* may enter the host by inhalation, ingestion, inoculation or transplacental transmission and cause disease. But, most of the organisms can produce infection only if they enter through a particular portal, e.g., *Salmonellae* can gain access through the intestinal tract but do not infect open wounds; *S. aureus* readily infects wounds but is unlikely to setup infection if ingested. The portal of entry may be located remotely from the part of the body, which ultimately bears the brunt of the disease; poliovirus enters the host through the pharynx and intestinal tract but the clinical effects of poliomyelitis spare the gastrointestinal tract and are largely confined to the central nervous system.

IN A NUTSHELL

1. The development or spread of an infectious disease requires an etiological agent; reservoir of the etiological agent; transmission of the agent from the reservoir to the new host.
2. Etiological agents include bacteria, viruses, fungi, protozoa, rickettsia and other unclassified organisms.
3. Man is the most important reservoir of microorganisms and macroorganisms causing infections. Other important reservoirs are animals and soil.
4. Microorganisms can exit the human body through coughing, sneezing, breathing, defecation, urine, cutaneous lesions and genital tract.
5. Microorganisms can invade a new host through inhalation, ingestion, injection or transplacentally.

Chapter 27.2

Laboratory Diagnosis of Infection

Sankar Sengupta

The microbiology laboratory plays a crucial role in the diagnosis of infectious diseases. Many tests are available for the detection of infection. These include microscopic demonstration, culture isolation, serological evidence and molecular techniques.

COLLECTION OF SPECIMENS

Body fluids, secretions and biopsy material can all be examined to detect pathogens, antigens or products or the immune response to them. Samples from the environment, e.g., water, food or soil, may also be examined. Some samples must be collected at a particular time; for example, blood for bacterial culture should be taken as the fever begins to rise. Special precautions must be taken to ensure survival of the pathogen and exclude contaminants, e.g., cleaning the perineum before collecting a midstream specimen of urine. Anaerobic species may die if exposed to atmospheric oxygen and survive better in samples of pus, rather than in swab specimens. Many pathogens such as *Neisseria* and most anaerobic species die quickly outside the body and must be transported to the laboratory without delay. *Neisseria gonorrhoeae* is susceptible to drying, so specimens likely to contain this organism should be inoculated onto microbiological medium near to the patient.

Universal precautions and laboratory safety Specimens may contain hazardous pathogens and must be handled with care. A system of universal precautions is employed to reduce the risk of transmitting blood-borne viruses. These are personal protective measures, taken in collecting and examining specimens irrespective of their source. The idea is to handle specimens on the assumption that they may contain a transmissible pathogen, rather than relying on clinical suspicion or written clinical details, which may be faulty or absent. For example, any sputum specimen is assumed to carry the risk of tuberculosis even if this is not the test requested.

DIRECT MICROSCOPIC EXAMINATION

Antony van Leeuwenhoek first saw microscopic *animalcules*, and Alexander Ogston, a surgeon, described the characteristic microscopic morphology of staphylococci in pus and discovered their role in pyogenic sepsis. The light microscope has since been indispensable in the study of microorganisms. The diagnosis of malaria or vaginal trichomoniasis, for instance, can be made while the patient waits at the clinic. Unlike culture, organism sought need neither multiply nor even be alive. Microscopy is especially useful for detecting organisms that are difficult or dangerous to grow.

Direct microscopy of unstained preparations Direct examination of unstained wet preparations is suitable for rapid diagnosis of fecal protozoa and helminths; organisms in vaginal discharge; and urine for bacteria and pus cells. Viruses can also be detected directly by electron microscopy, using a negative-staining technique. This technique is useful for detecting viruses with distinctive morphology, such as poxviruses in scrapings from the lesions of orf and *Molluscum contagiosum*, herpesviruses in vesicle fluid, or rotavirus in diarrhea stools.

Gram stain Dried preparations of specimens that are fixed to kill the organisms can be examined using simple stains, such as Gram stain, that dye the bacteria. This technique can demonstrate the shape of the bacteria and the capability of gram-positive bacteria

to retain the methylene blue dye. The Gram stain provides a rapid answer to the clinical question, Are there any organisms present? It is most useful when sterile fluids such as cerebrospinal fluid (CSF) or pleural fluid are examined. However, the sensitivity of Gram stain is relatively low and at least 10,000 organisms per mL must be present for a diagnosis to be made. Gram stain preparations can be made for the following fluids:

- Sterile fluids (CSF, ascites, pleural fluid)
- Sputum (to exclude poor-quality specimens)
- Pus from any site
- Urethral discharge.

Gram staining alone can rarely detect the organism specifically, because the morphology of bacteria is rarely diagnostic. Other simple stains include acridine orange, lactophenol blue to demonstrate the morphology of fungi, or India ink (to detect *Cryptococcus neoformans* in the CSF).

Ziehl-Nielsen (ZN) stain Specimens are stained with carbol-fuchsin, destained with an acid-alcohol solution and then counterstained with methylene blue. The lipid-rich mycobacterial cell wall retains the pink dye and organisms are seen as pink bacilli against blue background. This technique is useful in the diagnosis of mycobacterial infections, including tuberculosis and leprosy, and parasitic infections, such as cryptosporidiosis. A variation of this technique uses the naturally fluorescent substance auramine to stain the organisms. However, it lacks the specificity of the ZN stain.

Romanowsky stains Romanowsky stains, which color cytoplasm and chromatin, are widely used to demonstrate blood cells. Stains of this type are very useful for revealing blood parasites. In malaria or filariasis, Giemsa-stained smears not only demonstrate the presence of the organisms, but also permit speciation by displaying morphological details.

Immunofluorescence Direct immunofluorescence techniques detect organisms by their binding with fluorescence-labeled antibodies. This technique is both sensitive and specific and provides a rapid presumptive diagnosis. It can be applied to a wide range of specimens and is used in the diagnosis of upper respiratory tract virus infections including influenza, parainfluenza and respiratory syncytial virus, also measles and rabies. Some organisms detectable by direct immunofluorescence include viruses: parainfluenza viruses, respiratory syncytial virus; bacteria: *Legionella*, *Treponema pallidum*; and protozoa/fungi: *Giardia intestinalis*, *Pneumocystis jiroveci* (carinii).

CULTURE METHODS

Culture can aid diagnosis in bacterial, parasitic and viral diseases. In bacteriology, culture permits amplification of the number of bacteria. Isolating them on solid media makes identification and susceptibility testing possible. Bacterial culture is made possible by the use of agar, a gelatinous substance derived from seaweed, which melts at 90°C but solidifies at 50°C. It is highly stable, is rarely affected by organisms in cultures and can be mixed with nutrients, such as blood, serum and protein digests to make solid media. Bacteriological culture on solid agar is usually performed in Petri dishes. When prolonged culture is necessary, as in the diagnosis of mycobacterial or fungal infection, it is usually performed in sealed containers to prevent desiccation and the entry of contaminating organisms. The choice of medium and the conditions of incubation depend on knowledge of the organism's requirements for optimum growth. Three types of bacteriological media are used: (1) enrichment; (2) selective; and (3) indicator.

Enrichment media Enrichment media ensure that small numbers of fragile pathogens (e.g., *Neisseria* or *Vibrio spp*) can multiply sufficiently to be detected. They are useful when seeking to identify fastidious organisms such as *Streptococcus spp*, *Haemophilus influenzae* or *Bacteroides fragilis*. Enrichment media are made by adding blood, yeast extracts, tissue infusions, meat, etc. to simple

base media. Some enrichment media include materials to neutralize toxic bacterial products that would otherwise inhibit growth. An example of this is charcoal in the enrichment medium for *Bordetella*. The media may be solid, for example, blood agar or liquid, as with Robertson's cooked-meat broth. Liquid media are especially valuable for investigating body fluids that are normally sterile.

Selective media Selective media are used to identify a pathogen existing in a mixture of organisms. Many body sites, such as the upper respiratory tract or the gut, have normal resident flora and pathogens must be isolated from this bacterial competition. Selective media contain compounds such as chemicals (e.g., selenite F), dyes (crystal violet) or mixtures of antibiotics that selectively inhibit the normal flora, enabling the pathogen to grow. Although selective agents have their maximum effect on the unwanted organisms, some inhibition of the target organism inevitably occurs. Therefore, an enrichment medium should also be inoculated so that small numbers of pathogens can be detected. The examples of selective media for bacteriological culture from sites containing a normal flora are shown in **Table 1**.

Table 1 Selective media for bacteriological culture

Medium	Selective agent	Specimen	Organism/s sought
Crystal violet blood agar	Crystal violet	Throat swab	<i>Streptococcus pyogenes</i>
Desoxycholate citrate	Desoxycholate	Feces	<i>Salmonella</i> , <i>Shigella</i>
New York City medium	Lincomycin, colistin, amphotericin, trimethoprim	Urethral or cervical	<i>Neisseria gonorrhoeae</i>
Selenite broth	Selenite F	Feces	<i>Salmonella</i>
Sabouraud's agar	High dextrose content	Many	Fungi

Indicator media Indicator media are used to identify colonies of pathogens among the mixture of organisms able to grow on the selective medium. Many indicator media are also selective. An example of a selective indicator medium is MacConkey's agar, which uses bile salts to select for bile-tolerant enteric organisms.

Automation

Before automation of blood cultures became widely available, it was necessary to subculture each bottle manually after 12, 24 and 48 hours, and later as necessary. Nowadays, bacterial growth is detected by the microbial production of carbon dioxide or changes in the electrical impedance of the medium, indicating the need for subculture. These detection systems (e.g., Bactec and Bact-Alert systems) provide continuous monitoring of blood culture bottles allowing earlier subculture, identification and testing of pathogens. Such methods have been adapted to *Mycobacteria*, reducing the time taken to detect a positive culture from a mean of 5 weeks to 2 weeks or less.

Limitations of culture The main limitation of traditional bacterial culture is the time required for incubation. Bacterial culture is time-consuming and labor-intensive. Matrix-assisted laser desorption/ionization time-of-flight (MALDI-TOF) mass spectrometry (MS) offers the possibility of accurate, rapid, inexpensive identification of bacteria, fungi and mycobacteria within a few minutes.

Typing Microorganisms

Typing is the use of further identification methods to distinguish between strains of organisms within the same species. Methods of typing are numerous, ranging from simple biochemical to complex

genetic characterization. There are a wide range of phenotypic typing methods, including biochemical activity, serology and phage typing, which are often used in combination. Many laboratories still type enteric pathogens, such as *Shigella flexneri* or *Salmonella* using sets of antisera raised in mice or guinea pigs (serological typing). Such methods are being increasingly superseded by genetic methods. Many molecular typing methods are now used in clinical and research practice, much improving our ability to follow outbreaks and to study the epidemiology of infection. These include *nucleic acid typing methods* that use the activity of endonuclease enzymes to split the genome into a characteristic range of different-sized fragments. Genomic or plasmid DNA, or ribosomal RNA, is harvested from the test organisms and digested with restriction endonucleases. The resulting fragments are then separated by electrophoresis or pulsed-field gel electrophoresis (PFGE) to produce a pattern of bands. The variation in band patterns is called restriction fragment length polymorphism (RFLP). This approach has proved to be especially valuable in typing *Mycobacterium tuberculosis*. Polymerase chain reaction (PCR) methods can also be used to generate DNA, from a variable gene or genes, for RFLP typing. Multilocus sequence typing is a newer type of PCR-based typing method.

Culture of Protozoa, Helminths, Viruses

Culture of protozoa and helminths tends to be difficult and often produces no better diagnostic yield than microscopy. Viruses and chlamydiae are obligatory intracellular pathogens. So culture for these organisms must be performed in living cells or tissues. Viral growth in cell culture is further detected by virtue of one or more of the following properties: cytopathic effect, hemagglutination, antigen detection, or use of electron microscopy.

SEROLOGY

Serological techniques depend on the interaction between antigen and specific antibody. They are of particular value when the pathogen is difficult or impossible to culture, or is dangerous to handle in hospital laboratories. The process can be divided into two parts, first, the antigen-antibody interaction; and next, the demonstration of this interaction by a testing process. The sensitivity of a serological test depends partly on the specificity and strength of the antigen-antibody reaction, but mostly on the ability of the test system to detect the reaction. In older tests, antibody-antigen binding was detected by observing a natural consequence of this interaction: precipitation, agglutination or the ability of the antigen-antibody complex to bind and activate (fix) complement. Some laboratory tests based on these reactions are still in daily use. Newer tests use *labeled* immunoglobulin molecules to facilitate detection. The main methods employed are labeling with fluorescein or enzymes.

Agglutination Tests

Agglutination tests are used to identify the species or serotype of an infecting organism, by observing the aggregation of a suspension of bacteria in the presence of specific antibody. They can be performed on glass slides termed as *slide test* and are used for fecal pathogens such, as *Salmonella*, *Shigella* or respiratory pathogens e.g. *Streptococcus pneumoniae*. Agglutination is also used in biomarkers detection in fungal infections by *Candida* and *Aspergillus*. *Tube agglutination* is widely used in *Brucella* standard agglutination tests and Widal test for typhoid.

Coagglutination Specific antibodies can be attached to uniform latex particles, or killed protein A-possessing staphylococci. These particles will be agglutinated when they attach in large numbers to antigen molecules. In this way, otherwise soluble immune complexes may be detected in an agglutination reaction. Such latex and coagglutination techniques are used to detect the presence of the polysaccharide antigens of *S. pneumoniae*, *H. influenzae* type b, *Neisseria meningitidis* and *C. neoformans* in CSF, or *Streptococcus pyogenes* in throat swabs.

Indirect Fluorescent Antibody Tests

Specific antigen is fixed onto a multiwell microscope slide and patient's serum added. The slide is incubated, and then washed. Fluorescein-labeled antihuman immunoglobulin is then added, followed by further incubation. After a final wash, the slides are examined under ultraviolet illumination. Where antibodies from the patient's serum have bound to the antigen, the antihuman globulin will bind, and is indicated by apple-green fluorescence. Individual positive sera may be titrated. Indirect immunofluorescence is both sensitive and specific, but rather time consuming. It is used in the diagnosis of a number of infections, especially where the throughput of specimens is small, for instance in the diagnosis of syphilis [fluorescent treponemal antibody (FTA test)] or parasitic disease, such as leishmaniasis or amebiasis.

Enzyme-linked Immunosorbent Assay

Either the antigen or antibody in the reaction is allowed to bind to a solid phase, such as the walls of microtiter wells. Four variations of enzyme-linked immunosorbent assay (ELISA) are described:

Antibody-detecting ELISA tests In an antibody-detecting ELISA, specific antigen is coated onto the wells of a microtiter ELISA plate. The patient's serum is added and any specific antibody binds to the antigen (antibody-capture). The plates are then washed and enzyme labeled antihuman immunoglobulin is added. Plates are washed again and substrate for the enzyme is added. The enzyme-substrate reaction generates a color, which indicates the specific antibody interaction. The optical density of the wells is measured by an ELISA reader. A positive result can be determined by reference to control values. It is difficult to use an antibody capture assay to answer any question other than: Is there antibody present? If a diagnosis is to be made on a single specimen, specific immunoglobulin M (IgM) must be detected. This can be achieved by purifying an IgM fraction from the serum and retesting this in an antibody detection test. A simpler alternative is the IgM antibody-capture ELISA described below.

IgM antibody-capture ELISA By placing antihuman IgM antibody on the solid phase, it is possible to capture all IgM antibodies. After washing, labeled antigen is placed in the well so that if the serum contains antigen-specific IgM, the labeled antigen will bind. A positive result is detected by adding substrate, when a color will be produced by the enzyme-labeled antigen.

Antigen-capture ELISA Antibody to a specific antigen is bound on the solid phase. If antigen is present in the specimen, it will bind to the antibody. After washing, the bound antigen is then detected by enzyme-labeled specific antibody. The amount of antigen present can be quantified by reference to an antigen standard curve.

Competitive ELISA Competitive ELISA is a technique that is particularly useful for the measurement of antigen concentrations and is also used to detect antibodies or antibiotic concentrations.

Western Blotting (Immunoblotting)

Microbial proteins can be separated by sodium dodecyl sulfate-polyacrylamide gel electrophoresis (SDS-PAGE) and transferred electrophoretically to a nitrocellulose membrane. Strips of the membrane are exposed to the patient's diluted serum so that any antibodies specific to microbial proteins are bound, and can be detected using enzyme-labeled antihuman antibodies. The pattern of antibody recognition can be used to confirm a diagnosis and to demonstrate the stage of disease by the repertoire of antibody specificities that the patient has developed. This is useful in the diagnosis of Lyme disease, in which simpler serological techniques are unreliable. It is also used in the study of human immunodeficiency virus (HIV) seroconversion illnesses.

MOLECULAR AMPLIFICATION METHODS

Polymerase Chain Reaction

In a PCR, a reaction mixture consists of the specimen together with a pair of primers (short sequences of nucleotides specific for a nucleic acid sequence of the pathogen sought). Nucleotides and Taq polymerase (an enzyme that catalyzes the construction of DNA but is stable at high temperatures) are added. The reaction mixture is heated to separate all DNA strands. The primers bind to their target sequences, if they exist in the specimen, and are then annealed by cooling the mixture. The Taq polymerase adds nucleotides to make double-stranded DNA fragments. At the end of one cycle, there are, therefore, two copies of the nucleic acid sequences bound by the primers. The cycle of temperature manipulations is repeated, allowing exponential multiplication of these sequences. In positive reactions, the amplified sequences are detected by a variety of methods including the characteristic size of the product, or by hybridization.

A range of different nucleic acid amplification tests (NAATs) have followed the development of PCR. These use different reaction procedures, which all result in amplifying the target nucleic acid DNA. NAAT methods can be modified to demonstrate viral RNA by using reverse transcriptase to make DNA, which is then amplified in the usual way. It has been applied to the diagnosis of many viral diseases, including HIV, cytomegalovirus and some, such as hepatitis C, whose agent cannot be cultivated. NAAT methods have transformed viral diagnosis, allowing rapid detection of many pathogens. It is also transforming other disciplines in microbiology. A most important development has been the introduction of *real time* NAAT. For many pathogens, NAATs are significantly more sensitive than conventional culture methods, improving the diagnostic rate. An example of this is *Chlamydia*.

Applications of Molecular Amplification Methods

Detection of pathogens that grow slowly or that cannot be cultured A major advantage of NAAT is that it avoids the need to await growth of the organism in culture. This is especially important for virology where tissue culture is complex, expensive and slow and many common viruses cannot readily be cultured. Tuberculosis can be reliably diagnosed by NAAT in one day, compared to the many weeks required for culture. NAAT methods obviate the need for culture of dangerous organisms in the diagnosis of Lassa fever or anthrax. They have also been adapted for detection of bioterrorist attacks by allowing workers to detect suspected organisms in minutes using handheld devices.

Use of NAAT in routine bacteriology One of the disadvantages of NAAT is that it only detects the organisms that match the chosen test. In clinical practice, one of a range of organisms may be causing the patient's illness, and it would be impractical to apply numerous specific NAATs to search for them all.

Susceptibility testing The molecular basis of drug resistance is now becoming clear. For some organisms, the presence of a particular gene is associated with resistance to antimicrobial agents, for example, the *Pfmdr* gene in multidrug-resistant *Plasmodium falciparum*. HIV readily mutates to resistance, and the nucleotide sequence of the affected genes (protease and reverse transcriptase genes) can confirm the resistance and indicate which other drugs may also be affected. High-density DNA arrays can identify patterns of relevant genes in a microorganism, in a single procedure.

Response to treatment Amplification techniques can be useful in showing the early response to treatment. Examples include their use in measuring the response to antituberculosis therapy; the number of organisms in a respiratory sample can be estimated, using limiting-dilution PCR. A quicker alternative is to detect bacterial mRNA, which implies the presence of viable organisms allowing the success or failure of therapy to be judged. In managing HIV and hepatitis C infections, PCR is used to quantify the number

of viral genome copies in the serum (viral load). The progress of treatment can be followed by serial measurements.

IN A NUTSHELL

1. An important skill in clinical infectious diseases and microbiology is the choosing of appropriate diagnostic investigations.
2. Timely and accurate diagnosis depends on obtaining the correct specimen at the optimum time of collection. Specimens must be transported to the laboratory quickly and in conditions that maintain the viability of the organisms present or the integrity of the antigen or DNA sought.
3. Molecular diagnostic techniques now provide microbiologists with the possibility of providing a diagnosis more rapidly than was possible with culture-based methods.
4. In the laboratory, the correct diagnostic method must be used and the results effectively communicated to the doctor managing the case. This process depends on close cooperation between clinician, microbiologist and laboratory scientists.

Chapter 27.3

Antimicrobial Resistance

Anuradha De

Antimicrobial resistance (AMR) is a global problem in the hospitals as well as in the community and is listed at the top of the Centers for Disease Control and Prevention (CDC) list of emerging infectious threats to the public health. *Relentless and dizzying rise of antibiotic resistance* has contributed to the persistence of infections as a major cause of morbidity and mortality and have resulted in a number of microorganisms becoming resistant or multidrug resistant (MDR) to different antimicrobial drugs.

DEFINITION

Antimicrobial resistance is resistance of a microorganism to an antimicrobial drug, to which it was originally sensitive. Resistant organisms are able to withstand attack by antimicrobials (antibiotics) so that standard treatments become ineffective and infections persist, increasing risk of spread to others. The evolution of resistant strains is a natural phenomenon that happens when microorganisms are exposed to antimicrobial drugs and resistant traits can be exchanged between certain types of bacteria. The mechanisms of drug resistance are complex and microbes often outsmart humans. Hospitals are considered the epicenters of drug-resistant microorganisms.

EMERGING THREAT

The seriousness of AMR is reflected by a steadily increasing frequency of resistance over time among individual pathogens, increased presence of resistance among critical bacterial species causing common infections, and global extent of the resistance problem. The major cause of AMR is overuse and misuse of antimicrobial agents. Studies indicate that antibiotic use is unnecessary or inappropriate in as many as 50% of cases and this creates unnecessary pressure for the selection of resistant species. Also, there is an increased pressure to prescribe antimicrobial agents as a result of invasive medical technology and indwelling devices. Government policies also do not restrict direct over-the-counter purchase of antimicrobial agents by consumers, resulting in misuse. **Box 1** summarizes the reasons for AMR being a cause of global concern. Major concerns are listed in **Box 2**. **Figure 1** presents a timeline over which several antibiotics have developed resistance.

NATURAL VERSUS ACQUIRED RESISTANCE

Intrinsic or natural resistance Microorganisms naturally do not possess target sites for the drugs and, therefore, the drug does not affect them, or they naturally have low permeability to those agents because of the differences in the chemical nature of the drug and the microbial membrane structures, e.g., *Mycobacterium tuberculosis* is insensitive to tetracyclines. This type of resistance does not pose significant clinical problem.

Acquired resistance When a naturally susceptible microorganism acquires ways of not being affected by the drug to which it was earlier susceptible, the resistance is acquired. Resistance can be acquired by several methods:

Mutations in chromosomal genes or by the acquisition of mobile genetic elements, such as plasmids or transposons, which carry the antibiotic resistance genes. It may be due to sequential accumulation of chromosomal mutations in different drug-resistant genes, as in the case of multidrug-resistant tuberculosis (MDR-TB) and extensively drug-resistant TB (XDR-TB).

BOX 1 Why antimicrobial resistance is a global concern

- Infections caused by resistant microorganisms often fail to respond to the standard treatment, resulting in prolonged illness and greater risk of death
- Antimicrobial resistance reduces the effectiveness of treatment; patients remain infectious for a longer time, increasing the risk of spreading resistant microorganisms to others
- Antimicrobial resistance increases the costs of health-care by use of more expensive therapy, longer duration of treatment and increased cost of diagnostics
- Antimicrobial resistance threatens health security and damages global trade.

BOX 2 Major concerns in antimicrobial drug resistance

- Methicillin-resistant *Staphylococcus aureus* (MRSA) and methicillin-resistant *Staphylococcus epidermidis* (MRSE)
- Vancomycin intermediate-resistant *Staphylococcus aureus* (VISA) and vancomycin-resistant *Staphylococcus aureus* (VRSA)
- Methicillin-resistant coagulase-negative *Staphylococcus aureus* (MRCoNS).
- Inducible clindamycin resistance (ICR) in staphylococci and streptococci
- Vancomycin-resistant enterococci (VRE)
- Penicillinase-producing *Neisseria gonorrhoeae* (PPNG)
- The ESKAPE bugs—*Enterococcus*, *Staphylococcus*, *Klebsiella*, *Acinetobacter*, *Pseudomonas*, *Escherichia coli*/Enterobacter. These are responsible for two-thirds of all health-care-associated infections (HAIs)
- Multidrug-resistant gram-negative bacilli (MDR-GNB) producing extended spectrum beta (β)-lactamases (ESBLs); AmpC β -lactamases, Metallo- β -lactamases (MBLs), Carbapenemase-producing bacteria and *Klebsiella pneumoniae* carbapenemase (KPC)
- Multidrug-resistant tuberculosis (MDR-TB); and extensively drug-resistant TB (XDR-TB).

Genetic resistance, which is the transfer of genetic material from one bacterium to another and can occur by transformation/transduction/conjugation. For example, in 1959, the Japanese found *Shigella* species that were resistant to sulfonamides, streptomycin, chloramphenicol and tetracycline. The resistance was due to plasmid, which carried different antibiotic resistance genes. Streptomycin-resistance genes, *strA* and *strB*, can also be carried on plasmid.

Phenotypic resistance is due to changes in the bacterial physiological state, such as the stationary phase, antibiotic persists and the dormant state.

MECHANISMS OF ANTIBIOTIC RESISTANCE

Table 1 shows the mechanisms of drug resistance in different antibiotics. **Figures 2A and B** show the various mechanisms of antibiotic resistance. Other mechanisms are as follows:

- Alteration or overexpression of the drug target in cell wall—penicillin-binding protein (PBP) for methicillin-resistant *Staphylococcus aureus* (MRSA) and change of D-Ala-D-Ala to D-Ala-D-lactate target for vancomycin-resistant enterococci (VRE)
- Enzymatic inactivation—lincosamide and streptogramin inactivating enzymes
- Loss of enzymes involved in drug activation—catalase-peroxidase (KatG) is an enzyme involved in the activation of isoniazid (INH), which produces a range of reactive metabolites including reactive oxygen species and then reactive organic radicals, which then inhibit multiple targets, including mycolic acid synthesis.

Antibiotic deployment

Figure 1 Timeline of antibiotic resistance

Table 1 Mechanisms of drug resistance with different antibiotics

Antibiotic	Mechanism of drug resistance
Beta-lactams	<ul style="list-style-type: none"> Enzymatic inactivation by β-lactamases Altered penicillin-binding protein Reduced permeability or uptake by loss of porins leading to increased resistance Altered gram-negative outer membrane protein Active efflux
Macrolides	<ul style="list-style-type: none"> Alteration of target (ribosomal alterations) Active efflux by <i>mef</i> gene (macrolide efflux) Enzymatic inactivation
Chloramphenicol	<ul style="list-style-type: none"> Enzymatic inactivation by chloramphenicol acetyltransferase Active efflux
Tetracycline	<ul style="list-style-type: none"> Active efflux Insensitivity of 30S ribosomal subunit Enzymatic inactivation Ribosomal alterations

Sulfonamides and trimethoprim	<ul style="list-style-type: none"> Production of insensitive targets (dihydropterois synthetase and dihydrofolate reductase)
Quinolones	<ul style="list-style-type: none"> Mutations in DNA gyrase A and B subunits Decreased intracellular drug accumulation (active efflux)
Rifampicin	<ul style="list-style-type: none"> Mutations in <i>rpoB</i> gene encoding β-subunit of RNA polymerase
Polymyxins	<ul style="list-style-type: none"> Not defined

Beta-lactamases

Beta-lactamases are hydrolytic enzymes which cleave the β -lactam ring and are the primary mechanism of conferring bacterial resistance to β -lactam antibiotics such as penicillins and cephalosporins.

Extended spectrum β -lactamase (ESBL) was first observed in 1983 in *Klebsiella pneumoniae*. ESBLs are class A β -lactamases and may be defined as plasmid-mediated enzymes that hydrolyze oxyimino-cephalosporins and monobactams but not cephamycins or carbapenems. They hydrolyze penicillins, cephalosporins and monobactams, and are inhibited in vitro by clavulanic acid. They have the capacity to acquire resistance to other antimicrobial classes, such as the quinolones (ciprofloxacin), tetracyclines, trimethoprim-sulfamethoxazole and aminoglycosides (gentamicin and tobramycin), which further limits therapeutic options. ESBLs are primarily produced by the Enterobacteriaceae family and also by nonfermentative gram-negative bacteria.

The first plasmid-mediated metallo- β -lactamase (MBL) was reported in *Pseudomonas aeruginosa* from Japan in 1991. MBLs are metalloenzymes of Ambler class B and are clavulanic acid-resistant enzymes. They require divalent cations of zinc as cofactors for enzymatic activity and are universally inhibited by ethylenediaminetetra-acetic acid (EDTA). MBLs are commonly found in *P. aeruginosa* and *Acinetobacter baumannii*.

Figure 2A Mechanisms of antibiotic resistance

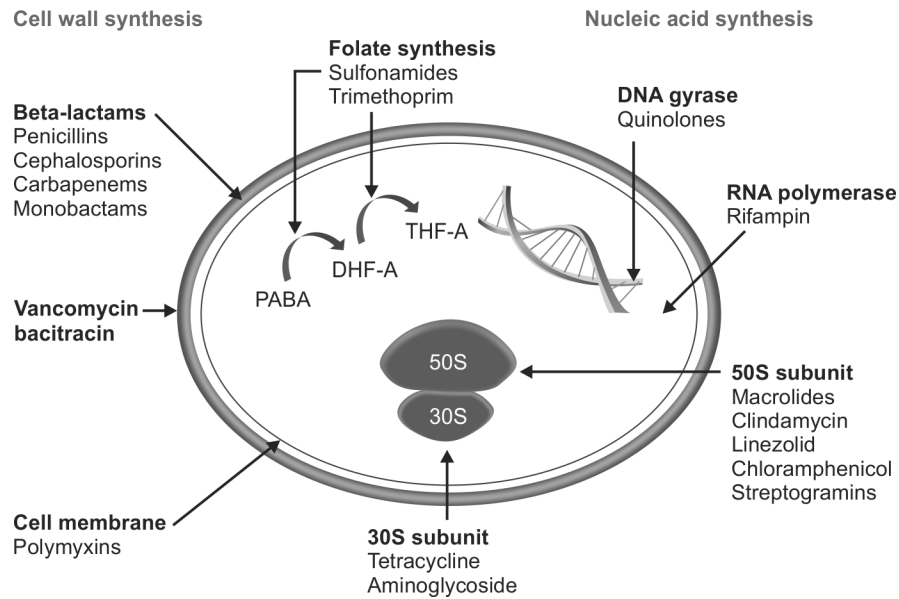

Figure 2B Mechanisms of antibiotic resistance

Klebsiella pneumoniae Carbapenemase

It was first described in North Carolina in 1999 and first isolate was reported in 2009 in sputum. *Klebsiella pneumoniae* carbapenemase (KPC) confers resistance to all β -lactams including extended spectrum cephalosporins and carbapenems. It occurs most commonly in *K. pneumoniae* or *Escherichia coli* and also reported in *K. oxytoca*, *Citrobacter freundii*, *Enterobacter* spp., *Salmonella* species and *Serratia* species. In KPC β -lactamases ~1–3% *K. pneumoniae* are resistant to carbapenems as well as to other β -lactams. They might appear susceptible to imipenem or meropenem, but with borderline MICs are usually ertapenem-resistant and susceptible only to colistin, tigecycline and select aminoglycosides.

ESKAPE Bugs

Vancomycin-resistant enterococci VRE emerged in late 1980s in France and England and subsequently has been isolated all over the world. Prolonged hospitalization, severe underlying diseases and/or immunosuppression, stay in intensive care areas, indwelling urinary or central venous catheters, etc. are the risk factors for the development of VRE.

Methicillin-resistant Staphylococcus aureus MRSA appeared in the early 1960s, soon after introduction of penicillinase-tolerant penicillins. Clones diversified and nosocomial pathogens spread into the community. Methicillin resistance now exceeds 50% in most tertiary care centers and is mainly accountable for Hospital-acquired MRSA (HA-MRSA), causing great morbidity and mortality, and thereby economic losses. This, coupled with the emergence of Community-acquired MRSA (CA-MRSA) in the recent years, poses serious clinical problems with global ramifications.

K. pneumoniae and *E. coli* ESBLs (~8–10%); 90% sensitive to carbapenems and tigecycline.

Acinetobacter traditionally infects patients in intensive care unit (ICU) and burn units. Drug resistance is a major problem in *Acinetobacter* infections, which are responsible for about 3% of all health-care-associated infections (HAIs). They are usually susceptible only to colistin.

Pseudomonas infections are usually seen in patients who are immunocompromised, debilitated, prior hospitalization, prior antibiotic therapy, trauma, etc. A particular problem is those patients on respirators and those with cystic fibrosis. One quarter of these is resistant to carbapenems.

Enterobacters also have developed broad-spectrum resistance to multiple classes of antibiotics. Tigecycline might work against these infections.

Multidrug-resistant Gram-negative Bacilli

In the recent years, the multidrug-resistant gram-negative bacilli (MDR-GNB) producing ESBLs, AmpCs and MBLs are also responsible for community-acquired infections, like skin and soft tissue infections, respiratory tract infections, urinary tract infections, etc. The major risk factors are prolonged stay in ICU, indwelling invasive devices and prior use of cephalosporins and other broad-spectrum β -lactam antibiotics. MDR-GNB cause great morbidity, mortality and economic losses. They can be effectively treated if identified properly and treatment initiated promptly, thus bringing down infection rates and preventing spread of MDR-GNB. Active surveillance of MDR-GNB in the community will help us in formulating an effective antibiotic policy based on the susceptibility pattern of MDR bacteria, which should be reviewed from time to time.

Table 2 shows the treatment and prevention of MRSA, VRE and MDR-GNB.

SURVEILLANCE OF ANTIMICROBIAL RESISTANCE

Surveillance involves the systematic collection and analysis of health-related data and dissemination to those who will use them in decision-making on public health issues. Ongoing and routine AMR surveillance enables analysis to be made of resistance rates to antimicrobials among bacteria infecting or colonizing individuals in given locations during defined time periods. Local surveillance units could be linked at national and international levels to provide national, regional and global surveillance information, insights and tools needed to guide policy on the appropriate use of antimicrobials and to inform and evaluate resistance containment interventions at local, national and global levels.

Table 2 Treatment and prevention of MRSA, VRE and MDR-GNB

	MRSA	VRE	MDR-GNB
Treatment	<p>Linezolid—protein synthesis inhibitor, used for nosocomial pneumonia and complicated skin infections</p> <p>Daptomycin—causes membrane depolarization in bacteria, so no membrane transport. It is used for bacteremia</p> <p>Clindamycin is not reliably bactericidal; D-test must be done; ~50% sensitive</p> <p>Vancomycin—acts by interfering with the construction of cell wall</p> <p>Combination of vancomycin, rifampin and cotrimoxazole</p> <p>Combination of fusidic acid and rifampin</p> <p>Third-line agents—trimethoprim-sulfamethoxazole (TMP-SMX)</p> <p>Tigecycline—works on efflux pumps</p> <p>Treatment for VISA infections are quinupristin/dalfopristin or rifampin or linezolid</p>	<p>Common sense, basic hygiene and disinfection practices can control the spread of MRSA</p> <p>Treatment options for vancomycin-resistant <i>E. faecium</i> are the newer antibiotics linezolid, daptomycin and tigecycline, but these drugs have not been studied extensively for use against these infections</p>	<p>Treating gram-negative bacterial infections can be difficult because of several unique features of these bacteria, e.g., the unique nature of their cell wall makes them resistant to several classes of antibiotics. Infections have typically been treated with broad-spectrum antibiotics, such as beta-lactams, followed by carbapenems. However, even these drugs have become ineffective against some bacteria, leaving health-care providers no choice but to use drugs like polymyxin B and colistin, which can have toxic side effects. Colistin is the last resort antibiotic for MDR <i>Pseudomonas aeruginosa</i>, MDR <i>Klebsiella pneumoniae</i>, MDR <i>Acinetobacter</i> species and MDR Enterobacteriaceae. <i>Proteus</i> species is inherently resistant to colistin</p>
Prevention	<p><i>Practising good hygiene:</i></p> <p>Enforcing hand hygiene by washing thoroughly with soap and water</p> <p>Use of alcohol-based hand sanitizers before eating and after using the restroom</p> <p>Use of gloves and not to touch unprotected body fluids</p> <p>Showering daily and after athletic practice or competition</p> <p>Keeping cuts and scrapes clean and covered with an antiseptic cream and a band-aid until healed</p> <p>Discarding used bandages and tape in garbage</p> <p>Avoiding contact with other people's wounds or bandages</p> <p>Using disposable items when treating MRSA patients</p> <p><i>Cleaning the environment:</i></p> <p>Cleaning surfaces first with wet mops and damp cloths, then disinfect</p> <p>Bleach + water 1:100/lysol/quaternary ammonium compounds</p> <p>Leaving surfaces wet for 10 minutes (if possible) or dry with paper towels</p>	<p>Proper hand hygiene, i.e., thorough washing with soap and water and then drying is the best way to prevent the spread of enterococci</p> <p>Use of alcohol-based hand rub or a household disinfectant or a mixture of one-fourth cup bleach and one quart of water to clean areas and surfaces that are touched frequently</p> <p>Wearing gloves when coming in contact with body fluids that may contain VRE</p> <p>Always washing hands after removing gloves</p> <p>The CDC Hospital Infection Control Program encourages hospitals to develop their own institution-specific plans, which should stress:</p> <p>Prudent vancomycin use by clinicians</p> <p>Hospital staff education regarding vancomycin resistance</p> <p>Early detection and prompt reporting of vancomycin resistance in enterococci and other gram-positive microorganisms by the hospital microbiology laboratory</p> <p>Immediate implementation of appropriate infection control measures to prevent person-to-person VRE transmission</p>	<p>Simple measures, such as hand-washing and health-care workers using barrier precautions can significantly reduce the spread of these bacteria</p> <p>A strict antibiotic policy should be followed in every hospital to prevent further spread of these MDR-GNB</p> <p>As these are multidrug resistant, they might pose a therapeutic challenge to clinicians as well as microbiologists</p> <p>Timely implementation of proper infection control practices reduce, eliminate and prevent establishment of MDR-GNB and prevent cross-contamination</p>

Abbreviations: MRSA, methicillin-resistant *Staphylococcus aureus*; VRE, vancomycin-resistant enterococci; MDR-GNB, multidrug-resistant gram-negative bacilli; VISA, vancomycin intermediate-resistant *Staphylococcus aureus*.

Strategic and Technical Advisory Group on Antimicrobial Resistance

The Strategic and Technical Advisory Group (STAG) on AMR in its first report in September 2013 specifically recommended that the World Health Organization (WHO) should lead in developing a global action plan to address AMR. **Table 3** shows the WHO Global Strategy for containment of AMR. **Figure 3** shows the steps to contain AMR. **Table 4** shows the core actions. Failure to implement simple infection control practices, such as hand-washing and changing of gloves before and after contact with each patient are common causes of infection spread in hospitals.

ANTIMICROBIAL STEWARDSHIP

Antimicrobial stewardship is a key component of a multifaceted approach in preventing emergence of AMR. Good antimicrobial stewardship involves selecting an appropriate drug and optimizing its dose and duration to cure an infection while minimizing toxicity and conditions for selection of resistant bacterial strains (giving maximum benefit and minimum of adverse events). A premium has been set on maintaining the effectiveness of currently available agents.

Several strategies, including prescriber education, formulary restriction, prior approval, streamlining and antibiotic cycling

Table 3 WHO Global Strategy for containment of antimicrobial resistance

S. No.	Strategy	Recommendations
1.	Education to patients and the general community	Educate patients and the general community on the appropriate use of antimicrobials, on the importance of measures to prevent infection, such as immunization, vector control, use of bednets, etc. on simple measures that may reduce transmission of infection in the household and community, e.g., hand-washing, food hygiene, etc. and discourage patients for self-initiation of treatment
2.	Education to prescribers and dispensers	Educate all groups of prescribers and dispensers (including drug sellers) on the importance of appropriate antimicrobial use and containment of antimicrobial resistance and infection control issues; promote targeted educational programs on the accurate diagnosis and management of common infections for all health-care workers, veterinarians, prescribers and dispensers
3.	Management, guidelines and formularies	Improve antimicrobial use by supervision and support of diagnostic and treatment strategies; audit prescribing and dispensing practices and utilize peer group or external standard comparisons to provide feedback of appropriate antimicrobial prescribing; encourage development and use of guidelines and treatment algorithms to foster appropriate use of antimicrobials
4.	Hospital management	Establish infection control programs based on current best practice for effective management of antimicrobial resistance in hospitals and ensure that all hospitals have access to such a program; establish effective hospital therapeutics committees for overseeing antimicrobial use in hospitals; develop and regularly update guidelines for antimicrobial treatment and prophylaxis; monitor antimicrobial usage, including the quantity and patterns of use and feedback results to prescribers
5.	Diagnostic laboratories	Ensure access to microbiology laboratory services that match the level of the hospital, e.g., secondary, tertiary; ensure performance and quality assurance of appropriate diagnostic tests, microbial identification, antimicrobial susceptibility tests of key pathogens; timely and relevant reporting of results; ensure that laboratory data are recorded, preferably on a database and are used to produce clinically and epidemiologically useful surveillance reports of resistance patterns among common pathogens, with feedback to prescribers and to the infection control committee
6.	Interactions with the pharmaceutical industry	Control and monitor pharmaceutical company promotional activities within the hospital environment and ensure that such activities have educational benefit
7.	Use of antimicrobials in food-producing animals	Require obligatory prescriptions for all antimicrobials used for disease control in food animals; in the absence of a public health safety evaluation, terminate or rapidly phase out the use of antimicrobials for growth promotion if they are also used for treatment of humans; create national systems to monitor antimicrobial usage in food animals; develop guidelines for veterinarians to reduce overuse and misuse of antimicrobials in food animals
<i>National governments and health systems</i>		
8.	Advocacy and intersectoral action	Making the containment of antimicrobial resistance a national priority; creating a national intersectoral task-force to raise awareness about antimicrobial resistance, preferably a government task-force which receives input from multiple sectors; allocating resources to promote the implementation of interventions to contain resistance, which should include the appropriate utilization of antimicrobial drugs, the control and prevention of infection and research activities; developing indicators to monitor and evaluate the impact of the antimicrobial resistance containment strategy
9.	Regulations	Establishing an effective registration scheme for dispensing outlets; limiting the availability of antimicrobials to prescription-only status and linking it to regulations regarding the sale, supply, dispensing and allowable promotional activities of antimicrobial agents; ensuring that only antimicrobials meeting international standards of quality, safety and efficacy are granted marketing authorization; introducing legal requirements for manufacturers to collect and report data on antimicrobial distribution (including import/export); creating economic incentives for appropriate use of antimicrobials
10.	Policies and guidelines	Establishing and maintaining updated national standard treatment guidelines (STGs) and encouraging their implementation; establishing an Essential Drugs List (EDL) consistent with national STGs and ensuring the accessibility and quality of these drugs; enhancing immunization coverage and other disease preventive measures, thereby reducing the need for antimicrobials
11.	Education	Maximizing and maintaining the effectiveness of the EDL and STGs by conducting appropriate undergraduate and postgraduate education programs of health-care professionals on the importance of appropriate antimicrobial use and containment of antimicrobial resistance; ensuring that prescribers have access to approved prescribing literature on individual drugs
12.	Surveillance of resistance, antimicrobial usage and disease burden	Developing reference microbiology laboratory facilities to coordinate effective surveillance of antimicrobial resistance among common pathogens in the community, hospitals and other health-care facilities; adapting and applying WHO model systems for antimicrobial resistance surveillance and ensuring data flow to the national intersectoral task-force, to authorities responsible for the national STGs and to prescribers; establishing systems for monitoring antimicrobial use in hospitals and the community, and linking these findings to resistance and disease surveillance data; establishing surveillance for key infectious diseases and syndromes according to country priorities, and linking this information to other surveillance data
13.	Drug and vaccine development	Encouraging drug development programs; providing incentives for industry to invest in the research and development of new antimicrobials; seeking innovative partnerships with the pharmaceutical industry to improve access to newer essential drugs
14.	Pharmaceutical promotion	Introducing requirements for pharmaceutical companies to comply with national or international codes of practice on promotional activities; ensuring that national or international codes of practice cover direct-to-consumer advertising, including advertising in the Internet

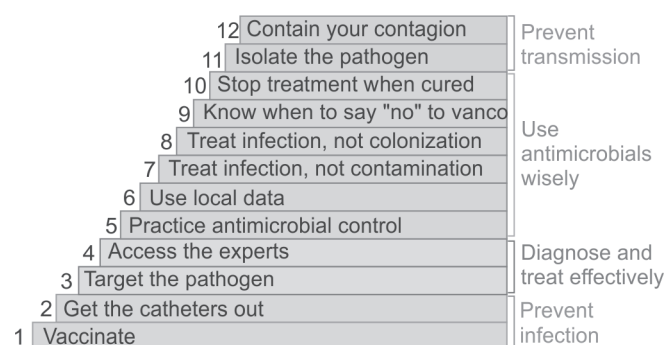

Contd...

Contd...

S. No.	Strategy	Recommendations
15.	International aspects of containing antimicrobial resistance	Encouraging collaboration between governments, nongovernmental organizations, professional societies and international agencies to recognize the importance of antimicrobial resistance and its containment and to implement strategies to contain resistance; encouraging all the above to support the establishment of networks, with trained staff and adequate infrastructures, who can undertake proper surveillance of antimicrobial resistance and antimicrobial use; supporting an international approach to the control of counterfeit antimicrobials in line with the WHO guidelines; encouraging innovative approaches to incentives for the development of new pharmaceutical products and vaccines for neglected diseases; establishing new and reinforcing existing programs for researchers to improve the design, preparation and conduct of research to contain antimicrobial resistance

Table 4 Core actions to counter antimicrobial resistance at global level

• Establish AMR surveillance and monitoring systems on a regular basis, which will help to formulate standard treatment guidelines
• Build laboratory capacity for rapid and reliable diagnostic testing by designating reference microbiology laboratories to establish quality assurance systems
• Improvement of existing treatment modalities by treating infections by nonantibiotic methods, e.g., natural peptides, vaccines, monoclonal antibodies; or use of combination regimens; or by identifying new antimicrobial drug targets; or to follow the principle of rotation of antibiotics to minimize antimicrobial resistance
• Development of new treatment modalities, e.g., phage therapy
• Mobilization of host defense mechanism through the development of vaccines
• The use of normal bacterial flora to suppress some pathogens
• Adhering to the list of <i>Critically Important Antibiotics</i> for human use only
• Treat infections not colonization, e.g., treat pneumonia, not the tracheal aspirate/endotracheal secretion; treat urinary tract infection, not the indwelling catheter; treat bacteremia, not the catheter tip or hub, etc.
• Initiation of studies to understand the causes of Fever of Unknown Origin (FUO)
• Introduction of IT-enabled softwares
• Community-based studies on the prevalence and susceptibility patterns of the circulating microbes (ESBLs, MRSA, MBLs, etc.) in population
• Engage in regional and global surveillance networks by participating in standard reporting of AMR and sharing AMR data
• Selected Infection Prevention Control (IPC) practices for prevention of emergence and spread of antimicrobial resistant microorganisms by hand hygiene, barrier precautions, biomedical waste management and prudent and appropriate use of antibiotics

**Figure 3** Steps to contain antimicrobial resistance

have been proposed to improve antibiotic use—a comprehensive program that incorporates multiple strategies and collaboration among various specialties within a given health-care institution. Computer-assisted software programs may be especially useful in implementing these comprehensive programs. The antimicrobial stewardship program has shown to improve appropriateness of antibiotic use and cure rates, decrease failure rates and reduce health-care-related costs. Presently, available data suggest that good antibiotic stewardship reduces rates of *Clostridium difficile*-associated diarrhea, MDR-GNB and VRE. **Box 3** shows the strategies of good antimicrobial stewardship.

BOX 3 Good antimicrobial stewardship strategies

- Education/guidelines for antimicrobial use: active methods work better than passive
- Formulary restriction: restrict dispensing of some antimicrobials to approved indications
- Review and feedback: daily review of targeted antimicrobials for appropriateness
- Computer-assisted strategies: using IT to implement previous strategies
- Antimicrobial cycling: scheduled rotation of antimicrobials used in a hospital or unit.

IN A NUTSHELL

1. Antimicrobial resistance is a global problem in the hospitals as well as in the community and is listed at the top of CDC list of emerging infectious threats to the public health.
2. Surveillance of AMR is required, which involves the systematic collection and analysis of health-related data and dissemination to those who will use them in decision-making on public health issues.
3. The antimicrobial stewardship program has shown to improve appropriateness of antibiotic use and cure rates, decrease failure rates and reduce health-care-related costs.
4. Every hospital should decide on appropriate antimicrobial stewardship programs so that AMR can be halted.

Chapter 27.4

Infection Control and Prevention

Jaydeep Choudhury

Infections remain a leading cause of disease in most part of the world. Most of the infections are acquired in the community. Those infections which manifest among patients only after 48 hours of stay in hospitals are called *nosocomial* or *health-care-associated infections (HCAIs)*. The infection may manifest even after discharge to home. For obvious reason, the profile and severity of these infections are different than those acquired in the community. These infections lead to significant morbidity, mortality and economic burden, which is beyond those expected from the patients' underlying disease. As these infections are acquired under health-care, they are preventable.

MAGNITUDE OF THE PROBLEM

Nosocomial infections can occur as outbreaks or as sporadic cases. Outbreaks are highly visible; but sporadic infections are far more important. Most nosocomial infections originate from neonatal intensive care unit (NICU), pediatric ICU (PICU), hematology-oncology and neonatal surgery. In Western world, the nosocomial infection rate is 5–10 infections per 100 patient admissions; in the developing world, the rate can be 25% or more. The distribution of infections by anatomic site in acute care hospitals of developed countries is shown in **Table 1**. In developing countries, the bloodstream infections are less and gastrointestinal infections and postoperative wound infections are more common. Bloodstream and pulmonary infections carry the highest mortality rates (25–30%).

Table 1 Distribution of infection by anatomic site in developed countries

Site	Percentage (%)
Urinary tract	35
Postoperative wound	25
Bloodstream	10
Pneumonia	10
Others	20

PATHOGENESIS

Nosocomial infections can be *exogenous* or *endogenous*. In the former, the pathogens gain direct access to the patient from the environment, either animate or inanimate source and initiate disease. Endogenous infections are derived from the patient's own microflora. Primary endogenous infections refer to pathogens derived from patient's own normal flora. In secondary endogenous, the pathogen colonizes the patient, becomes part of the normal flora and subsequently causes infection. Primary endogenous infections are always sporadic.

Mode of Spread

Nosocomial infections are transmitted by contact, vehicles, air or vectors. Person-to-person transmission through the hands of hospital staff or patients is the most important mode. Infrequent hand-washing by overburdened staff and staff having contact with increased number of patients are the most important factors. Vehicles of transmission of nosocomial infection could be food,

water, intravenous solutions or blood and blood products. Medical equipment, contaminated thermometers and other devices are also equally important. Rodents and cockroaches are known vectors of infection.

Pathogens Involved

About 65–70% of pediatric nosocomial infections are bacterial, 50% are gram-positive and about 20% are gram-negative. The distribution varies according to the age of the patient, site of infection and prevailing pathogen in the hospital. Coagulase-negative *Staphylococcus* is particularly associated with infections related to intravascular catheters.

Children are at greater risk of viral infections. Respiratory syncytial virus and adenovirus cause outbreaks of nosocomial respiratory tract infection. Rotavirus and hepatitis A virus cause gastrointestinal tract infection. Varicella-zoster infection outbreak in NICU is also well documented.

PREVENTION OF NOSOCOMIAL INFECTIONS

Under any situation, more than 20% of all hospital-acquired infections can be prevented. Most of the interventions are simple, basic and related to individual health-care worker. Careful hand-washing, appropriate isolation, use of gloves when required and proper use of devices go a long way in the prevention of nosocomial infections. Other systemic issues that also require attention are as follows:

- Availability of soap and water at all times which should be placed in a convenient location for easy access
- Surgical patients should receive preoperative antibiotics (1–2 hours before incision, not greater than 2 hours and never delayed to one after incision)
- Isolation of patients with communicable disease. Various modes of isolation in different diseases are shown in **Table 2**.

Table 2 Isolation and precautions for infection control

Modes of isolation	Diseases	Methods
Strict isolation	Diphtheria, rabies	Single room, gown, gloves, mask. Hand-washing. Proper care of contaminated articles
Contact isolation	Bronchiolitis, conjunctivitis, MRSA	Single room, mask for close contacts. Gloves for touching infected area. Strict hand-washing. Proper care of contaminated articles
Respiratory isolation	Measles, whooping cough, meningococcal diseases	Single room, mask for close contacts. Strict hand-washing. Proper care of contaminated articles
Enteric isolation	Rotavirus, shigellosis, any diarrhea	Preferably single room, gowns if soiling, gloves for handling infective material. Strict hand-washing. Care of contaminated articles
Blood and body fluid precautions	Hepatitis B, HIV	Isolation not indicated, no masks, gloves for handling blood or body fluid. Gowns if soiling likely. Proper care of contaminated articles
Protective isolation	Immunosuppressed patients	Single room, gowns, gloves, mask. Strict hand-washing. Sterilized food and drink

Abbreviations: MRSA, methicillin-resistant *Staphylococcus aureus*; HIV, human immunodeficiency virus.

Infection Control Program

Health-care authority should take the initiative to develop a national or a regional program to support hospitals and health-care system in reducing the risk of HCAs. The program must focus on a definite objective consistent with the national or local health-care objectives. It should aim to develop and regularly update guidelines for health-care surveillance, prevention and practical application; facilitate access to materials essential for hygiene; monitor nosocomial infections; plan effective interventions; and train health-care professionals in infection control. Components of infection control are listed in **Box 1**.

Infection control practices can be placed in two categories, *standard precautions*, which must be applied to all patients at all times, regardless of diagnosis or infectious status and *additional precautions*, which are specific to modes of transmission of the disease.

BOX 1 Important components of infection control

- Basic measures for infection control
- Education and training of health-care workers
- Protection of health-care workers
- Routine practice for infection control—antisepsis and asepsis, antibiotic usage, handling and use of blood products, hospital waste management
- Surveillance
- Incidence monitoring
- Outbreak investigation
- Research.

Standard Precautions

Standard precaution includes simple, cheap and feasible measures like hand hygiene, environmental cleaning and waste handling. Strict adherence to these methods is the key to successful control of HCAI. Components of standard precautions are listed in **Box 2**.

BOX 2 Components of standard precautions for infection prevention

- Hand hygiene—hand-washing and antisepsis
- Use of personal protective equipment when handling organic materials, like blood or other body fluids, excretions and secretions
- Appropriate handling of patient care equipment and soiled linen
- Prevention of needle stick or sharp injuries
- Environmental cleaning and management practices
- Appropriate handling of waste
- Patient placement and transportation.

Hand Hygiene

Proper hand hygiene practices minimize microorganisms acquired on the hands during daily health work and when there is contact with blood, body fluids, secretions, excretions and contaminated equipment or surfaces. Hands should be washed in all the above situations and also in between attending patients. It is also important to wash hands after removing the gloves as gloves do not provide complete protection against hand contamination. The following are the indications for hand-washing with soap and water strictly for 2 minutes.

- At the entry of ICU (PICU, NICU)
- Before performing any invasive procedures before wearing gloves
- When hands are visibly soiled with dirt or organic material
- After touching soiled linen or other items, mucous membranes, wounds, dressings even if the hands are not soiled
- After examining a culture-proven sepsis patient
- Every time after removing gloves.

Alcohol-based hand rubs have been shown to be superior to soap in decreasing the bacterial colony counts. They are

recommended to be used after drying hands following hand washing and also routinely before and after every patient contact. Alcohol-based hand antiseptics are not effective on hands that are visibly dirty or contaminated with organic material unless they are first washed with soap and water.

Use of Personal Protective Equipment

Using personal protective equipment provides a physical barrier between microorganisms and the wearer. It offers protection by helping to prevent microorganisms from contaminating hands, eyes, clothing, hair and shoes and be transmitted to other patients and staff. Personal protective equipment include gloves, mask, gown, cap or hair cover, protective eye wear (goggles), apron, and boots or shoe covers. Personal protective equipment should be used by health-care workers who provide direct care to patients and support staff including medical aides, cleaners, laundry staff, who may have contact with patient's organic materials. It should also be used by laboratory staff who handle patient specimens and family members who provide care to patients.

Handling of Patient Care Equipment and Soiled Linen

Patient care equipment soiled with organic materials should be handled with care in order to prevent exposure to skin and mucous membranes, clothing and the environment. All reusable equipment should be cleaned and reprocessed appropriately before using on another patient. Used linen that is soiled with organic material should be handled with care to ensure that there is no leakage of organic fluid into the surrounding surface. The method and periodicity of decontamination depends on the equipment type and is shown in **Table 3**.

Prevention of Needle Stick/Sharps Injuries

Needles, scalpels and other sharp instruments or equipment should be used with utmost care. Used disposable syringes and needles, scalpel blades and other sharp items should be placed in a puncture-resistant container with a lid that closes. Extra care should be taken while cleaning sharp reusable instruments or equipment. Needles should never be recapped or bent. Sharps must be appropriately disinfected and/or destroyed as per the national standards or guidelines.

Patient Placement

Spacing between beds There should be adequate spacing between each bed to reduce the risk of cross infection due to direct or indirect contact or droplet transmission. Optimum spacing between beds is 1–2 meters.

Single rooms Single rooms reduce the risk of transmission of infection from the source patient to others by reducing direct or indirect contact transmission. Wherever feasible, single rooms should have hand-washing facilities and toilet facilities.

Cohorting If single rooms are not available, patients infected or colonized by the same organism can be cohorted. If cohorting is used during outbreaks, these room/s should be in a well-defined area (a designated room or designated ward), which can be clearly segregated from other patient care areas in the health-care facility used for noninfected patients.

Transportation of Patients

If transportation is required, suitable precautions should be taken to reduce the risk of transmission of microorganisms to other patients, health-care workers or the hospital environment. For example, while transporting an open case of pulmonary tuberculosis (TB), placing a surgical mask on the patient is an appropriate precaution.

Table 3 Patient care equipment and linen decontamination

Item	Activity	Periodicity
Incubators, warmers, trolleys	In use: detergent and water Not being used: 2% glutaraldehyde	In use: daily Not being used: dismantle weekly and clean with 2% glutaraldehyde
Ventilator body	2% carbolic acid	Once daily
Infusion pumps/monitors	Clean with moist cloth	Once daily
Ambu bag and accessories	Dismantle, wash visible contamination, then 2% glutaraldehyde for 30 minutes Dismantle, wash visible contamination, then 2% glutaraldehyde for 6 hours	After each use Once weekly
Rubber and plastic tubing	2% glutaraldehyde for 6 hours	Once daily
Humidity bottles, suction bottles and oxygen hoods	Clean with detergent	Once daily
Laryngoscopes	Clean with spirit 2% glutaraldehyde for 30 minutes	After each use Once daily
Thermometer, stethoscopes, measuring tapes	Wipe with spirit	Before and after each use
Weighing machines	Wipe with moist cloth	Once daily
Saturation probes	Preferably use disposable, while reusing wipe with spirit	Before and after each use
BP cuff	Ideally use disposable, while reusing wipe with spirit	Before and after each use
Procedure sets	Autoclave	After each use
Linen and gowns	Manually clean and then autoclave	After each use
Feeding utensils	Wash with detergent, boil for 20 minutes	Before each use

Environmental Cleaning and Management Practices

A clean environment plays an important role in the prevention of HCAI. Routine cleaning is important to ensure a clean and dust-free hospital environment. Most patient-care areas should be cleaned by wet mopping. The use of a neutral detergent solution improves the quality of cleaning. Areas visibly contaminate with blood or body fluids should be cleaned immediately with detergent and water. Isolation rooms and other areas that have patients with known transmissible infectious diseases should be cleaned with a detergent/disinfectant solution at least daily. All horizontal surfaces and all toilet areas should be cleaned daily.

Air ventilation Ventilation systems should be designed and maintained to minimize microbial contamination. The air conditioning filters should be cleaned periodically and fans that can spread airborne pathogens should be avoided in high-risk areas. High-risk areas such as operating rooms, critical care units and transplant units require special ventilation systems. Filtration systems (air handling units) designed to provide clean air should have high-efficiency particulate air (HEPA) filters in high-risk areas. Unidirectional laminar airflow systems should be available in appropriate areas in the hospital construction. Special air handling is needed for the operating room and for immunocompromised patients.

Handling of Waste

Hospital waste is a potential reservoir of pathogenic microorganisms and requires appropriate, safe and reliable handling. The main risk associated with infection is sharps contaminated with blood. There should be a person or persons responsible for the organization and management of waste collection, handling, storage and disposal. Waste management practices must meet national and local requirements. Steps in the management of hospital waste are described below:

Segregation and collection Infectious waste should be collected and segregated from noninfectious waste in dedicated containers

at the source. This prevents contamination by infectious waste to other hospital waste.

Transportation Waste should be transported in a dedicated trolley. They should be cleaned regularly.

Storage Waste should be stored in specified areas with restricted access. Sharps should be stored in sharps containers. Sharps containers should be made of plastic or metal and have a lid that can be closed. They should be marked with the appropriate label or logo, e.g., a biohazard symbol for clinical (infectious) waste.

Treatment Each health-care facility should identify a method for the treatment of infectious waste. This may consist of transportation of infectious waste to a centralized waste treatment facility or on-site treatment of waste.

Final disposal Sharps should be autoclaved after chemical treatment and landfill or microwave. Deep burial should be done in a secure area. Burial should be 2–3 meters deep and at least 1.5 meters above the groundwater table. Anatomical parts, animal carcasses, cytotoxic drugs (residues or outdated) and toxic laboratory chemicals other than mercury should be incinerated. Patient-contaminated nonplastics and nonchlorinated plastics may be also incinerated. Plastics, nonplastics contaminated with blood, body fluids, secretions and excretions and infectious laboratory wastes also should not be incinerated. Such wastes should be treated by steam sterilization in autoclavable bags or microwave treatment. Chemical treatment with 1% hypochlorite or a similar disinfectant is recommended. However, excessive use of chemical disinfectants should be avoided. Radioactive waste should be dealt with according to national laws. Treatment and final disposal of waste is shown in **Table 4**.

Additional Precautions

Airborne Precautions

Airborne precautions are designed to reduce the transmission of diseases spread by the airborne route. Airborne transmission

Table 4 Treatment and final disposal of waste

Color coding	Waste	Treatment and final disposal
Yellow (solid infectious)	Human tissues, organs, body parts Microbiology and biotechnology waste (wastes from lab cultures, specimens, live-attenuated vaccines, etc.) Waste items contaminated with blood and body fluids including cotton dressings, soiled plaster casts, linen	Incineration
Red (solid noninfectious)	Waste generated from disposable items other than sharps like tubings, catheters, IV sets	Disinfect by chemical treatment (1% hypochlorite) then either autoclave and later shredding
Blue (sharps)	Needles, syringes, scalpel blades, glass, etc.	Disinfect by chemical treatment (1% hypochlorite) then either autoclave and later shredding
Black (other wastes)	Discarded medicines and left-over foods	Taken for landfill

occurs when droplet nuclei (evaporated droplets) less than 5μ in size are disseminated in the air. These droplet nuclei can remain suspended in the air for a long time. Diseases which spread by this mode include open/active pulmonary TB, measles, chicken pox and other viral infections.

Droplet Precautions

Droplets are usually generated from the infected person during coughing, sneezing, talking or when health-care workers undertake procedures, such as tracheal suctioning. Droplet transmission occurs when there is adequate contact between the mucous membranes of the nose and mouth or conjunctivae of a susceptible person and large particle droplets ($> 5\mu$). Diseases, which are transmitted by this route include viral and bacterial pneumonias, pertussis, diphtheria, influenza type B, mumps and meningitis. In these cases, patients should be placed in a single room (or in a room with another patient infected by the same pathogen). Health-care persons should wear a surgical mask.

Contact Precautions

Diseases which are transmitted by this route include colonization or infection with multiple antibiotic-resistant organisms, enteric infections and skin infections. Here patient should be placed in a single room (or in a room with another patient infected by the same pathogen). Clean, nonsterile gloves and gown should be used when entering the room. Limit the movement and transport of the patient from the room; patients should be moved for essential purposes only. If transportation is required, use precautions to minimize the risk of transmission.

4. Nosocomial infections are transmitted by contact, vehicles, air or vectors.
5. About 65–70% of pediatric nosocomial infections are bacterial, 50% are gram-positive and about 20% are gram-negative.
6. More than 20% of all hospital-acquired infections can be prevented. Most of the interventions are simple, basic and related to on individual health-care worker.
7. Hand-washing is the single most important step for prevention.
8. Hospital waste is a potential reservoir of pathogenic micro-organisms and requires appropriate, safe and reliable handling.

Section 28 FEVER

Section Editor Piyush Gupta

Chapter 28.1

Approach to a Child with Fever

Bhavna Dhingra, Piyush Gupta

Fever, in common parlance, is an elevation of body temperature above normal, but not all causes of temperature elevation constitute fever (e.g., heat stress and heat illness). Fever is an elevation of core body temperature as part of a specific biological response, mediated by cytokines and controlled by the central nervous system (CNS). It is a characteristic feature of many diseases, both infectious and noninfectious, and it involves activation of various physiological, endocrinological and immunological systems.

Normal body temperature follows a circadian rhythm and varies between 36.6°C in the morning to 37.9°C in the evening. Body temperature is controlled by the thermoregulatory center located in the preoptic anterior hypothalamus, which balances heat production, derived primarily from metabolic activity in muscle and the liver, with heat dissipation from the skin and lungs to maintain the temperature in a steady range. Oral temperature is generally 0.6°C (1.0°F) lower than rectal temperature because of mouth breathing, which is particularly important in patients with respiratory infections and rapid breathing. Lower esophageal temperature reflects core temperature, and tympanic membrane (TM) temperature readings also approximate to core temperature. Beyond the newborn period, infants and young children generally have higher body temperatures due to the greater surface area to body weight ratio and the higher metabolic rate than older children and adults.

DEFINITION

A clinically significant fever is generally defined as a rectal temperature of 38°C (100.4°F) or higher. This is equivalent to an oral temperature of 37.5°C (99.5°F), and axillary (armpit) temperature of 37.2°C (99°F). Fever above 41.5°C (107°F) is called hyperpyrexia and may lead to irreversible organ damage.

PATHOPHYSIOLOGY OF FEVER

Fever is induced by pyrogens. Bacteria, fungi, viruses, malignancies, connective tissue disorders, certain drugs, and trauma may endogenously stimulate production of pyrogens.

- Common *endogenous pyrogens* include interleukin 1 (IL-1), tumor necrosis factor (TNF) and interferon. Other endogenous pyrogens include IL-6, IL-11, leukemia inhibitory factor (LIF), ciliary neurotropic factor (CNTF) and oncostatin-M. Large amounts of IL-6 circulate in nearly all febrile diseases, and IL-6, induced by IL-1 or by the combination of IL-1 and TNF, accounts for most clinical fevers.
- *Exogenous pyrogens* include the bacterial cell wall component lipopolysaccharide (LPS), enterotoxins, and exotoxins. Exogenous pyrogens can induce production of endogenous pyrogens via activation of Toll signaling, and both endogenous and exogenous pyrogens stimulate the synthesis of prostaglandins (PG).

Prostaglandin E2 (PGE2) is the ultimate endogenous pyrogen. It resets the temperature of the hypothalamus.

Fever is the result of a series of events that begins peripherally with the synthesis and release of IL-1 and other cytokines by phagocytic cells in the blood or tissues. **Flow chart 1** illustrates the pathophysiology of fever.

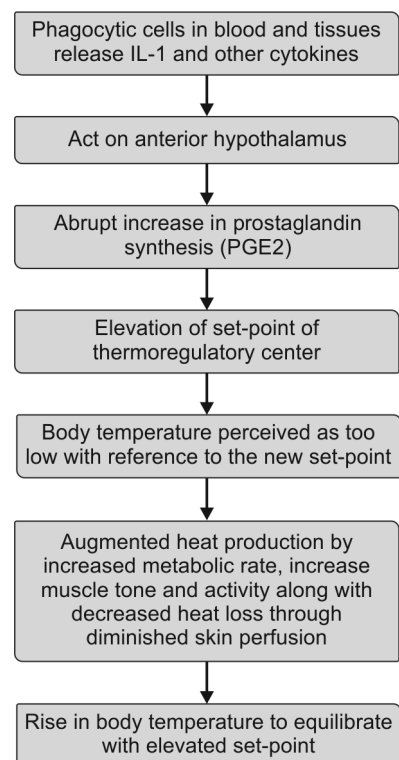

ADVANTAGES OF FEVER

The survival of some pathogenic bacteria or viruses is impaired at temperatures in the range of 40°C (104°F). Many pathogenic bacteria require iron for their growth, and fever is associated with a decrease in serum iron and a simultaneous increase in the iron-binding protein, ferritin, resulting in low levels of free iron in the blood. It has been suggested that this response is a coordinated host defense mechanism meant to deprive bacteria of free iron. Enhancement of several human immunologic functions occurs at moderately elevated temperatures, e.g., increased lymphocyte transformation response to mitogen, increased bactericidal activity of polymorphonuclear leukocytes, and increased production of interferon with increasing temperature. Beyond 40°C, most of the functions decline below baseline levels.

DISADVANTAGES OF FEVER

Fever is associated with an increased metabolic rate, increased oxygen consumption, increased carbon dioxide production, and

Flow chart 1 Pathophysiology of fever

increased demands on the cardiovascular and pulmonary systems. Fever often makes patients uncomfortable. Fever can precipitate febrile convulsions in children between 6 months and 5 years of age. Fever can aggravate cerebral injury.

ETIOLOGY OF FEVER

Fever is probably the most common presenting complaint in pediatric practice and is associated with a wide variety of illnesses. The most common cause of fever in children is a viral infection. In viral infection, fever is usually short-lived and signs are usually more generalized than those with bacterial infection. Common viral and bacterial illnesses like upper respiratory infections (URI), gastroenteritis, ear infections, croup, and bronchiolitis are the most likely illnesses known to cause fevers of short duration. Viral fevers usually resolve in about a week, persistence of fever beyond this time requires a detailed work-up. Bacterial URIs may be difficult to distinguish from viral URIs but the presence of pus points in the tonsil and unilateral involvement of ears points towards a bacterial etiology. Other common infective causes that need to be looked into are malaria, urinary tract infections, sepsis, abscesses, etc.

EVALUATION OF A FEBRILE CHILD

Performing a detailed and thorough history and physical examination is the first and most important component of the diagnostic evaluation of a febrile child. The next steps are to (i) localize the fever to a particular organ system by presenting complaints; and to (ii) identify the probable etiology of fever, depending upon its duration, pattern and clinical examination.

History

The history should include questions regarding characteristics of fever (onset, intensity, duration, frequency and pattern of fever—continuous, remittent or intermittent); how was the temperature assessed—perceived manually or documented by a thermometer along with the site of documentation; localizing symptoms of fever; recent exposures like vaccination, animal/insect bites, or receipt of blood transfusion or biological product; exposure to a family member with fever or any infectious disease; past history of any significant illnesses such as tuberculosis, urinary infections, congenital heart disease, and surgical procedure; any history of travel in the recent past; history of an underlying chronic disease, and medication history. History of recurrent episodes of fever may give a clue to certain cyclic causes of fever. Ask for other system-related symptoms. Enquiry about specific symptoms may help in localizing the disease to a particular system.

Examination

The physical examination should begin with a general assessment of the patient's appearance, activity, vital signs, and growth parameters. It is a good idea to evaluate the child during febrile period as the presence or absence of few signs during the febrile phase may provide certain clues to diagnosis, e.g., absence of sweating in anhidrotic ectodermal dysplasia. Absence of malaise or other generalized signs in a child with a history of high fevers can signal factitious fever.

Identify the Etiology of Fever

Short duration fever Fever of less than 2 weeks duration is usually infectious in origin, and due to viruses, bacteria or protozoa. Many of these patients recover completely, even before a precise diagnosis is made or treatment is given. These children may present with or without localizing manifestations. Every effort should be made to identify and localize the system involved, based on the localizing symptoms, as shown in **Table 1**.

Table 1 Determining etiology of fever based on presenting features

<i>Cough and coryza</i>	<i>Viral fever</i>
Rash	Exanthematous illnesses like measles, rubella, chickenpox, erythema infectiosum, roseola infantum, herpes simplex; other illnesses like meningococemia, dengue, Henoch-Schönlein purpura, leukemia, and Kawasaki disease
Ear pain	Acute suppurative otitis media (ASOM)
Skin boils	Abscess, pustules, cellulitis, impetigo
Seborrheic dermatitis (± ear discharge)	Langerhans cell histiocytosis
Periungual desquamation with strawberry tongue	Kawasaki disease
Throat pain, difficulty in swallowing, cervical nodes	Pharyngotonsillitis
Stridor, dysphonia	Laryngitis, tracheitis, croup, epiglottitis, diphtheria
Fast breathing and cough, wheezing, chest in drawing, chest pain	Pneumonia, bronchiolitis, pleural effusion, tuberculosis
Joint swelling, pain or limited movements	Septic arthritis, rheumatic fever, tubercular arthritis, connective tissue diseases
Vomiting	Gastritis, gastroenteritis, viral hepatitis, meningitis, enteric fever, UTI
Diarrhea	Gastroenteritis, enteric fever, dysentery
Jaundice	Hepatitis, cholecystitis, malaria
Pallor, rash, bleeding, lymphadenopathy	Leukemia, infectious mononucleosis
Urinary frequency, burning micturition, crying during micturition, hematuria	Urinary tract infection, cystitis
Chills or pallor or jaundice	Malaria, hepatobiliary causes
Altered sensorium, seizures, neurological deficits, meningeal signs	Meningoencephalitis (bacterial, viral, tubercular), cerebral malaria, enteric encephalopathy, brain abscess
Abdominal pain	Gastroenteritis, appendicitis, liver abscess, hepatitis, cholecystitis, cholangitis, intra-abdominal/pelvic abscess, pyelonephritis

Prolonged fever Fever lasting for more than 2 weeks requires a different approach. Infections still remain the most important cause of prolonged fever; however, noninfectious causes are also responsible. Common causes of prolonged fever are listed below:

- **Infections:** Tuberculosis, HIV, urinary tract infections, chronic fungal infections, etc.
- **Inflammatory disorders:** Rheumatoid arthritis, systemic lupus erythematosus, Kawasaki disease and other connective tissue disorders including polyarteritis nodosa, Behcet disease, Wegner granulomatosis.
- **Malignancies:** Lymphoma (including Hodgkin disease), leukemia, hepatoblastoma, Wilms tumor, neuroblastoma, brain tumors.
- **Endocrine causes:** Thyrotoxicosis, diabetes insipidus.
- **Hematological and immune deficiency disorders:** Spherocytosis, agranulocytosis, hemolytic anemia; Langerhans cell histiocytosis, disorders of T- or B-cells; disorders of phagocytosis.

- *Neurologic disorders:* Familial dysautonomia, hypothalamic and third ventricle lesions; anhidrotic ectodermal dysplasia.
- *Miscellaneous causes:* Drug fever, periodic fever, factitious fever.

Box 1 provides a detailed list of common causes of fever associated with hepatosplenomegaly, rash, or lymphadenopathy. When fever has been persistent for a week, and no cause has been

BOX 1 Etiology of fever with rash, lymphadenopathy and hepatosplenomegaly

Fever with Hepatosplenomegaly

- *Infectious causes:* Malaria, enteric fever, kala-azar, tuberculosis, infectious mononucleosis, brucellosis, echinococcosis, rickettsial diseases, TORCH infections, dengue, septicemia, and infective endocarditis
- *Malignancies:* Leukemias, lymphomas, histiocytosis, infantile heman-gioendothelioma, hepatoblastoma, and metastases
- *Connective tissue diseases:* Systemic lupus erythematosus (SLE); systemic juvenile idiopathic arthritis (JIA), sarcoidosis, scleroderma, and rheumatic fever
- *Chronic hepatitis/chronic liver disease:* Autoimmune hepatitis, chronic hepatitis B/C, and Wilson disease.

Fever with Rash

- *Infectious causes:* Meningococemia, dengue, measles, rubella, varicella, roseola infantum, erythema infectiosum, herpes simplex, and lupus vulgaris
- *Malignancies:* Leukemia and histiocytosis
- *Vasculitis:* Henoch-Schönlein purpura, Kawasaki disease, rheumatic fever, systemic JIA, and SLE.

Fever with Lymphadenopathy

- Suppurative lymphadenitis (bacterial, often accompanying pharyngitis, tonsillitis, dental infections, scalp infections)
- Tuberculosis
- Lymphoma (Hodgkin and non-Hodgkin lymphomas)
- Histiocytosis
- Acute lymphoblastic leukemia (ALL)
- HIV infection
- Connective tissue disorders such as systemic JIA or sarcoidosis
- Kawasaki disease
- Rosai-Dorfman disease.

found, serious consideration should be given to hospital admission to confirm pyrexia and initiate investigations. Appropriate laboratory testing as per the merit of each case may include: complete blood counts with peripheral smear, ESR, CRP, urinalysis and urine culture, blood cultures and serologic tests when appropriate (e.g., for enteric fever, malaria, dengue, leptospirosis, TORCH infections, rickettsial infections, *Coccidioides immitis*, *Cryptococcus neoformans*, *Borrelia burgdorferi*, *Treponema pallidum*, and HIV). Radiological investigations may include X-ray chest; ultrasonography, CT and MRI, as indicated. Other common though invasive investigations include bone marrow examination, lumbar puncture, cytopathology, and examination of ascitic/pleural/joint fluids.

IN A NUTSHELL

1. Fever is a symptom of an underlying disease, which may be infective or noninfective.
2. Fever results due to a change in the set point of hypothalamic thermoregulatory center.
3. The most common cause of fever in the young child is usually a self-limiting viral infection.
4. A detailed and thorough history and physical examination is the most important component in the evaluation of a febrile child.
5. Duration of fever and associated symptoms aided by appropriate investigations can help in localizing cause of fever.

Chapter 28.2

Fever: General Principles of Management

Piyush Gupta, Bhavna Dhingra

All fevers do not need to be treated, and when treated, the primary objective of treating fever should be to make the child comfortable, and not the normalization of body temperature. Antipyresis can be achieved by nonpharmacological measures and/or drugs. Antipyretics may help in overall management of a febrile child but do not appear to affect the recurrence of febrile seizures.

NONPHARMACOLOGICAL ANTIPYRESIS

Nonpharmacological methods include environmental modifications, increased fluid intake, and mechanical cooling.

Environmental Modifications

Place the child in cool and airy environment (21–22°C) which enhances heat loss by convection. Minimal clothing; i.e., dressing the child in only one layer, is advocated to enhance heat loss. Some theories support a gentle body massage to dilate the cutaneous blood vessels which further increases heat dissipation.

Hydration

As fever increases, the metabolic rate of the body also goes up. For each 1°C rise of temperature above 37.2°C, there is an increase in insensible water loss of 7 mL/kg body weight/day. Hence, extra fluid intake is advised in febrile patients. For each 1°C of increase in temperature, a 12% increase in fluid intake is recommended.

Mechanical Cooling (Hydrotherapy or Sponging)

It is considered the mainstay of nonpharmacological antipyresis. External cooling lowers the temperature of febrile patients by evaporation, conduction, and convection. Evaporation is rated as the most effective physical mean of promoting heat loss in febrile children because it has the least capacity to induce shivering. External cooling acts by impairing the overwhelming effect or mechanisms evoked by elevated thermoregulatory set point, rather than by lowering the elevated set point. The capacity of external cooling to lower core temperature is limited because it induces both cutaneous vasoconstriction and shivering. Therefore, unless concomitant antipyretic therapy or other pharmacological methods are used to abolish shivering, external cooling is vigorously opposed in febrile patients by thermoregulatory mechanisms endeavoring to maintain elevated temperature.

External cooling with ice is the treatment of choice for heatstroke and other forms of heat illness, but is more discomforting. For fever, external cooling is indicated only in specific situations, and with tepid rather than cold water. Some infants with infection may also have a component of heat illness from over-wrapping, dehydration, or drugs such as atropine. Sponging should be done by continuous wiping of the body with tepid water (28–30°C) from head to toe for 15–20 min. Sponging action ensures that water film is constantly moving thus maximizing heat conduction. Tepid sponging acts by conduction of heat from the warm skin to water. An absorbent towel should be soaked, rinsed and placed on the legs, trunk and forehead in order to reduce the body temperature. Hydrotherapy should be continued till the body temperature comes down to 38°C. Indications for sponging is summarized in **Box 1**. Studies indicate that hydrotherapy alone is clearly inferior to antipyretics for reduction of fever for periods longer than

BOX 1 Indications for sponging with lukewarm water in fever

- Febrile delirium
- Febrile seizure
- Fever > 41.1°C
- Patients with neurologic disorders, because many of these children have abnormal temperature control and respond poorly to antipyretic agents
- Children with hypersensitivity to antipyretic agents
- Children with severe liver disease.

30 min after initiation of treatment. External cooling may, however potentiate the activity of antipyretics.

Results of randomized trials comparing the combination of antipyretics and physical methods with antipyretics alone have provided mixed results. In 4 out of 7 such studies the combination treatment was superior to use of antipyretics alone for reduction of temperature during first 30 min of initiation of therapy and overall. In other 3 studies both modes of treatments were equally effective in lowering temperature. It is recommended to administer antipyretic drugs at least 30 min before sponging.

The main disadvantage of hydrotherapy is patient discomfort and shivering. Shivering not only impedes cooling during fever but also imposes considerable metabolic burden. Studies in volunteers have shown that shivering increases the oxygen consumption, respiratory minute volume, respiratory quotient, increase in percentage of carbon dioxide in exhaled air during exposure to cold and increase in mean arterial pressure. Perhaps in febrile patients with cardiovascular disease external cooling can cause coronary artery vasoconstriction by cold press or response and thus decrease coronary perfusion. Sponging, though rapid in reduction of temperature, has an ill sustained effect.

PHARMACOLOGICAL ANTIPYRESIS

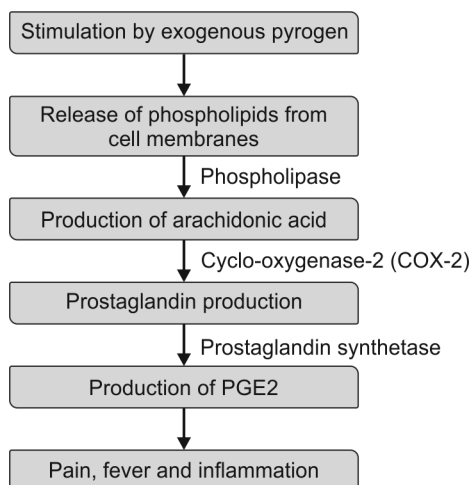

Antipyretic agents are administered to provide symptomatic relief in children with fever. Keeping in mind that fever results from change in the set temperature of the hypothalamic thermoregulatory center, it seems logical to bring down the temperature by restoring the hypothalamic set-point to normal.

Commonly used agents to achieve antipyresis include paracetamol, ibuprofen, and aspirin. Aspirin was the first antipyretic used in children. However, after reports of its association with causation of Reye syndrome, aspirin is not recommended for controlling fever in children. Mefenamic acid and nimesulide are the other drugs used infrequently to control fever.

Mechanism of Action

The antipyretic medications act via the arachidonic acid pathway (**Flow chart 1**). Arachidonic acid is a substrate for both cyclooxygenase-2 (COX-2) and a second isoform of the enzyme, COX-1. COX-2 is the principal mediator of the inflammatory response, resulting in production of prostaglandin₂ (PGE₂). COX-1 products, on the other hand, function primarily in renal function, vascular homeostasis and gastrointestinal cytoprotection. Central inhibition of COX is responsible for the antipyretic effects of paracetamol. Relatively weaker inhibition of splenic COX accounts for its relatively poor anti-inflammatory response. Paracetamol is nearly as effective as aspirin and 10% as effective as indomethacin in inhibiting central COX but only 5% as effective as aspirin and 0.02% as effective as indomethacin in inhibiting peripheral COX.

Ibuprofen is a competitive inhibitor of the COX enzymes, in that it competes with arachidonic acid for binding to the catalytic site on COX, thereby preventing prostaglandin synthesis. This is a reversible process. Unlike paracetamol, ibuprofen acts peripherally and lacks specificity for either COX isomer. Ibuprofen therefore has antipyretic, analgesic and anti-inflammatory actions.

Flow chart 1 The arachidonic acid metabolism pathway

Dosing and Toxicity

Paracetamol

Paracetamol is recommended in a dose of 15 mg/kg at 4–6 hourly intervals not exceeding 60 mg/kg/day. Antipyretic effect begins within 30–60 min, approximately 80% of children will experience a decreased temperature within this time frame. Paracetamol reduces the temperature by 1–2°C after 2 hour of intake. The rate of fall of temperature is directly related to the degrees above which initial temperature was above baseline. Greater the initial temperature, greater is the fall after drug intake and vice versa. Hence, drug administration in low grade temperature may not lead to any significant fall and antipyretic treatment in high grade fevers (> 104°F) would result in reduction of temperature by less than 1°C, failing to touch the baseline.

Ibuprofen

Ibuprofen can also be used as a first line antipyretic. Efficacy of paracetamol and ibuprofen has been compared in a number of studies, and some have shown greater antipyretic effect with 10 mg/kg of ibuprofen as compared to 15 mg/kg of paracetamol. Ibuprofen has the advantage of longer duration of antipyresis (8 h) as compared to paracetamol (4 h). Recent evidence indicates that there is no difference in the safety and effectiveness of paracetamol and ibuprofen in the care of a generally healthy child with fever. There is evidence that combining these 2 drugs is more effective than using them alone. However, this should not be followed as a routine because of associated risk of inappropriate dosages. The practice of alternating ibuprofen and paracetamol has limited value.

Nimesulide

Nimesulide has a superior efficacy when compared to paracetamol, aspirin, naproxen and mefenamic acid. Also the advantage of reduced frequency of dosing (2–3) exists with its use. However, use of nimesulide in children is associated with potentially fatal adverse effects resulting in hypothermia, hepatotoxicity, and renal damage.

Mefenamic Acid

Mefenamic acid is a reversible competitive inhibitor of COX-1 and COX-2 enzymes and has analgesic, antipyretic, and anti-inflammatory properties. It is very effective in control of high fever in a dose of 6–7 mg/kg/dose (20 mg/kg/day in three divided doses), usually a single dose suffices and can later be followed by paracetamol after 6–8 hour. Its main side effects are diarrhea, hemolytic anemia, thrombocytopenia and drowsiness.

Choice of Antipyretic

The decision regarding the choice of antipyretic should be based on personal experience, scientific data regarding efficacy, safety, duration of effect, and cost. In therapeutic dosages aspirin is more toxic and causes gastritis, gastrointestinal bleeding, impaired platelet function, diminished urinary excretion of sodium, Reye syndrome and blunted immune response. These side effects are known to occur less frequently with ibuprofen and none with paracetamol. Paracetamol can be safely used in children with asthma, with sensitivity to aspirin or ibuprofen, coagulation disorders, peptic ulcer or reflux esophagitis. Thus paracetamol is considered to be the safest antipyretic in children at therapeutic dosages. Hepatotoxicity appears to be the most serious and well-documented toxicity associated with use of paracetamol in children. Concern has been raised over the gastrointestinal disturbance and nephrotoxicity with ibuprofen; hence caution is encouraged when using ibuprofen in children with dehydration. In the overdose situation, the toxicity of paracetamol is not only reached much earlier, but is also more severe and more difficult to manage as compared with an overdose of ibuprofen.

The most commonly used and preferred mode of administration of antipyretics is the oral route. Rectal suppositories may be used in children with febrile seizures or unconscious patients. Parenteral (intramuscular or intravenous) administration of paracetamol may be used in cases where quick relief of fever is required or when oral administration is not possible, e.g., comatose children. The dose of intravenous paracetamol is 7.5 mg/kg/dose (max. 30 mg/kg/day) for neonates and infants and 15 mg/kg/dose for older children (max. 60 mg/kg/day) to be given as an infusion.

Parental Education

Fever is the most common complaint for which medical attention is sought by the caregivers. It also causes considerable parental anxiety and concern; therefore, appropriate counseling of parents and caregivers is a must. Parents need to be explained that fever is a protective response of body and helps to fight the disease. Medical personnel need to emphasize and deal with issues, such as what is fever, what is high grade fever, advantages and disadvantages of fever, when and which fever should be treated and how, the danger signs associated with fever, and when to seek medical help.

HEAT HYPERPYREXIA

Heat hyperpyrexia is not an unusual cause of fever in tropical countries where ambient temperature may go as high as 45°C. Heat hyperpyrexia may occur even without exposure of the child to the direct sunlight. The predisposing factors include high temperature and humidity in the environment, unsuitable clothing, dehydration and debilitating illness, such as malaria, pneumonia, measles, and renal disorders. Invariably, heat hyperpyrexia is associated with cessation of sweating. Children with ectodermal dysplasia and absence of sweat glands are more prone to develop episodes of heat hyperpyrexia.

The onset of high fever may be quite sudden. The rectal temperature may exceed 42°C to 43°C. The skin appears hot and dry (without sweating). Tachycardia and tachypnea are present. The loss of consciousness occurs early. The patient may develop peripheral circulatory failure and hemorrhages. Headache, faintness, abdominal discomfort and delirium are usually complained of. The liver and kidney failure may complicate heat hyperpyrexia.

Management

When the temperature exceeds 41°C, body of the child below the neck should be immersed in the cold water without further delay to prevent irreversible brain damage. The parents should be reassured that this seemingly drastic measure will not induce shock. Ice cold bath does not cause significant vasoconstriction. The rectal temperature should be recorded continuously and the hydrotherapy should be discontinued as the temperature falls below 38°C.

IN A NUTSHELL

1. Fever *per se* is just a symptom of underlying illness and not a disease itself.
2. All fevers do not need treatment. The aim of treating fever is not normalization of body temperature.
3. Febrile children should be advised to drink plenty of water and wear loose comfortable clothing.
4. Medicines should be used only when indicated. Paracetamol (15 mg/kg) is the safest antipyretic in children. Ibuprofen is an alternative. Aspirin and nimesulide should not be used in children.
5. Hydrotherapy with tepid water may be useful when used in combination with pharmacological antipyresis.
6. Explain to parents that febrile seizures occur in minority of children, are benign and do not cause any permanent brain damage or epilepsy.
7. Close monitoring is required in children with past history of febrile seizures.
8. Parents should be taught the emergency management of febrile seizures.

Chapter 28.3

Fever without Focus

Piyush Gupta, Bhavna Dhingra

Fever without focus in a child is defined as a rectal temperature of 38°C or higher as the only presenting symptom and can be sub-categorized into *fever without localizing signs* (FWLS) and *fever of unknown origin* (FUO).

FEVER WITHOUT LOCALIZING SIGNS

Children presenting with history of acute onset of short duration fever (usually less than a week) as the only presenting complaint without any signs or symptoms localizing to any organ system are categorized as having fever without localizing signs. This presents a diagnostic challenge in children less than 36 months of age. These children represent an important group because of higher risk of occult bacteremia and serious bacterial infections (SBI) (range 5–20%). Therefore, it may sometimes become essential to start specific and empirical treatment without establishing an etiological diagnosis. As the etiology of this entity and risk of SBI is variable in different age groups, these children are usually subclassified into the following three categories:

1. Neonates (up to 1 month of age).
2. Infants, 1–3 months of age.
3. Infants, 3–36 months of age.

There are certain high-risk groups of children who are at increased risk of SBI and require a more aggressive outlook. These include children presenting with: hyperpyrexia (> 40°C); fever with petechiae; and immunocompromised patients with asplenia, sickle cell disease, complement deficiency states, agammaglobulinemia, hypogammaglobulinemia, congenital heart disease, malignancy, or AIDS.

Neonates (Birth-1 Month of Age)

Newborns presenting with fever without localizing signs present a diagnostic dilemma for the treating clinician. They have a very limited number of signs of infection and that too are nonspecific. Immune response is also not mature. It is difficult to differentiate between dehydration fever, a self-limited viral illness, and SBI. SBI ranges from occult bacteremia, pneumonia, meningitis, urinary tract infection, and enteritis, to osteomyelitis, and septic arthritis.

Any newborn or young infant presenting with fever should be hospitalized and after control of ambient environmental temperature and adequate hydration with increased frequency of breastfeeding, if the baby is still febrile—possibility of SBI should be entertained even in an apparently healthy neonate. All such neonates should be subject to a septic screen which includes complete blood counts with band form count, urine microscopy, blood culture, urine culture, chest X-ray, and peripheral smear for malarial parasite. Lumbar puncture and cerebrospinal fluid analysis (cell counts, glucose, protein, Gram stain and culture) should be undertaken in children with lethargy or refusal to breastfeeding.

Etiology

Haemophilus influenzae B and *Streptococcus pneumoniae* are the two most important causes of SBI in India, besides *Klebsiella*, *Staphylococcus aureus*, and *Escherichia coli*. *Listeria monocytogenes* and perinatally acquired *Herpes simplex virus* (HSV) infection have also been implicated. Malaria should also be considered a strong possibility in endemic areas.

Management

After obtaining relevant investigations, empirical antibiotic therapy should be initiated at the earliest with combination of ampicillin and cefotaxime or monotherapy with ceftriaxone (100 mg/kg per day) and modified later as per the reports of the sepsis screen and cultures.

Fever in the Young Infant 1–3 Months of Age

Self limited seasonal viral illnesses are the most common cause of fever without localizing signs in this age group. The possibility of SBI should always be entertained in any febrile child between 1 month and 3 months of age and the following conditions should be ruled out: otitis media, pneumonia, skin and soft tissue infections, omphalitis and urinary tract infections especially in uncircumcised boys and children with urinary tract anomalies.

Risk Stratification

Febrile infants less than or equal to 3 months with diminished spontaneous activity, lethargy, respiratory compromise (tachypnea, chest retraction and grunting), diminished muscle tone, mottled cool extremities, irritability, weak sucking are at high-risk. Infants 1–3 month of age with fever who appear well and had been previously healthy, and have a normal physical examination, can be categorized as at *low-risk* or *high-risk* for serious bacterial infections by certain investigations. **Table 1** lists the various criteria used for identifying children 1–3 months at low-risk of SBI.

Etiology

The most common implicated organisms are Group B *Streptococcus*, *E. coli*, *S. aureus*, *S. pneumoniae*, *H. influenzae*, *Neisseria meningitidis* and enterococci. Pyelonephritis is the most common SBI and may be seen in well appearing as well as ill appearing children between 1 month and 3 months of age presenting with fever without localizing signs.

Management

Febrile children, 1–3 months of age who present with fever without localizing signs must be evaluated for sepsis by complete blood count, lumbar puncture, blood culture, urinalysis, urine culture and chest radiograph. Ill appearing infants require immediate hospitalization and prompt institution of empirical parenteral antimicrobial therapy. Ampicillin with either cefotaxime or ceftriaxone is an effective combination. Vancomycin should be included if possibility of meningitis with penicillin resistant *S. pneumoniae* is suspected. Antimicrobials can be modified as per the culture and sensitivity reports.

In well appearing infants a watchful observation without antibiotics may be planned and a sepsis screen obtained, although a lumbar puncture may be deferred. A mandatory follow-up after 24 hours must be ensured. Prior to initiation of antibiotics in the event of clinical deterioration, a lumbar puncture should always be done.

Fever without Localizing Signs in 3–36 Months Old Children

Viral infections are responsible for majority of children having nonlocalizing fever in this age group. Serious bacterial infection can also occur due to *S. pneumoniae*, *Neisseria*, and *H. influenzae*. Risk factors for occult bacteremia in these children include rectal temperature > 39°C, WBC counts > 15000/mm³, raised ESR, and elevated C-reactive protein. Rectal temperature > 40°C and WBC count > 25000/mm³ indicate a higher probability of serious bacterial infection. Important bacterial infections include otitis media, pneumonia, sinusitis, enteritis, urinary tract infection,

osteomyelitis and meningitis. Pneumococcal bacteremia can resolve spontaneously in about one-third of cases or can lead to development of localized infections, e.g., meningitis, pneumonia, cellulitis, pericarditis, osteomyelitis or septic arthritis. Management options are detailed in **Flow chart 1**. Infants with moderate to high

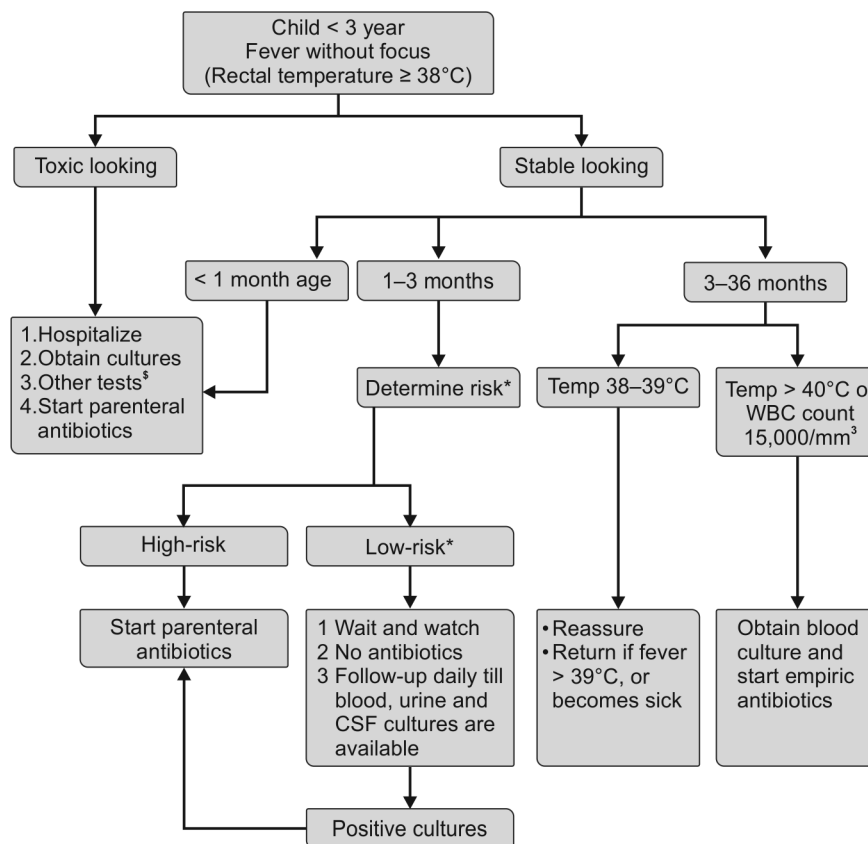

risk factors should be treated with ceftriaxone (50–80 mg/kg/day in one or two divided doses IV or IM). In infants below 4 weeks of age, ampicillin (50–100 mg/kg/day IM or IV two divided doses) should also be added to cover *Listeria monocytogenes* and enterococci, which are not sensitive to ceftriaxone.

Table 1 Low-risk criteria in 1–3 months old children with fever without localizing signs

	<i>Philadelphia protocol</i>	<i>Pittsburgh guidelines</i>	<i>Rochester criteria</i>	<i>Boston criteria</i>
General appearance	Well	Well	Well	Well
Physical examination	Normal	Normal	Normal	Normal
Complete blood count WBC/mm ³	< 15,000	5000–15000	5000–15000	< 20,000
I:T neutrophil ratio absolute band count	< 0.2	< 1500/mm ³	< 1500/mm ³	
Urine examination	< 10 WBC/HPF No bacteria on Gram stain	9 WBC/mm ³ No bacteria on Gram stain	< 10 WBC/HPF at 40X	Negative leukocyte esterase
Cerebrospinal fluid (If bloody tap)	< 8 WBC/mm ³ No bacteria on Gram stain	5 WBC/mm ³ No bacteria on Gram stain WBC:RBC ≤ 1:500		< 10 WBCs/mm ³
Chest radiograph	No infiltrates	No infiltrates		
Stool examination	No RBC, few or no WBC	5 WBC/HPF with diarrhea	< 5 WBC/HPF if diarrhea	
				Caretaker contactable telephonically

Abbreviations: WBC: white blood cells; RBC: red blood cells; HPF: high power field; I:T, immature: total.

Flow chart 1 Management of fever without focus in young children
(Reproduced from Gupta P. *Textbook of Pediatrics*. New Delhi: CBS; 2013)

*Determine risk based on history, examination, and laboratory studies:

Low-risk: Normal history and physical examination; WBC 5000–15000/mm³; band cell < 1500/mm³ urine pus cells < 10/hpf; stool pus cells < 5/hpf; normal chest radiograph; and CSF < 8 lymphocytes/mm³.

[§]Other tests include WBC count; urine and stool microscopy; chest X-ray; CSF Gram stain. Cultures include that of blood, urine, and CSF.

IN A NUTSHELL

1. Children presenting with fever without localizing signs carry high chances of occult bacteremia and serious bacterial infection (SBI).
2. Newborns or young infants with fever should be hospitalized and dehydration fever ruled out, before starting empirical therapy.
3. Well appearing, 1–3 months old febrile children should be categorized into low-risk and high-risk categories, based on certain criteria.
4. Empirical antibiotic therapy should be started in children at high-risk of serious bacterial infections/occult bacteremia.

Chapter 28.4

Fever of Unknown Origin

Bhavna Dhingra, Piyush Gupta

Fever of unknown origin (FUO) is defined as fever (rectal temperature $> 38^{\circ}\text{C}$) documented by a health-care personnel, for which no cause is identifiable after 3 weeks of outpatient evaluation and after 1 week of evaluation as an inpatient that includes a careful history and physical examination and initial laboratory assessment.

Nosocomial or health-care-associated FUO refers to hospitalized children receiving acute care in whom infection or fever were absent on admission but in whom a fever of 38°C or more occurs on several occasions, for at least a week.

Neutropenic FUO is defined as multiple readings of more than 38°C in a child with absolute neutrophil count less than $500/\text{mm}^3$, after at least 3 days of investigations including at least 48 hours of incubation of cultures.

HIV-related FUO is defined as a temperature of more than or equal to 38°C on multiple occasions for more than or equal to 3 weeks as an outpatient and more than 1 week as an inpatient in a patient with confirmed HIV infection.

Fever of unknown origin needs to be differentiated from fever without localizing signs as their differential diagnoses and most frequent causes are distinct. Children with FWLS usually need immediate evaluation and empirical antibiotic therapy, whereas those with FUO generally do not need an emergency assessment and antibiotics. The major hurdle in establishing a diagnosis is that the salient features rendering specific disorders clinically recognizable are absent or subtle. There is no *one fits all* algorithm available for evaluation and the clinician needs to work-up each case on its own merit.

ETIOLOGY

Fever of unknown origin is usually an uncommon presentation of a common illness. Infectious diseases, connective tissue diseases and autoimmune disorders are the most common causes of FUO in children. Malignancies are responsible for a lesser number of cases

as most children with malignancies present with other systemic signs or suggestive laboratory abnormalities. Drug fever, factitious fevers and periodic fever syndromes are responsible for a few cases of FUO. **Table 1** lists the common causes of FUO in children.

Epidemiologically relevant infections must be considered first in differential diagnosis and ruled out by appropriate clinical, laboratory and radiological evaluation. Hidden deep seated abscesses, e.g., pelvic, subdiaphragmatic, perinephric, subphrenic, psoas, retroperitoneal, mediastinal, dental, brain and hepatic should always be looked for and excluded. Subacute bacterial endocarditis should be high on the suspicion list especially in the setting of a pre-existing cardiac disease.

Nosocomial infections with unusual organisms, e.g., anaerobic bacilli should be considered in differential diagnosis of a patient having received various antibiotics, especially aminoglycosides, for several days in the hospital. Factitious fever should be considered, if fever persists for more than 6 months without diagnosis.

APPROACH TO DIAGNOSIS

Unless the child is acutely ill, the evaluation for FUO generally is done on an outpatient basis. If outpatient evaluation fails to disclose a cause for the fever, inpatient evaluation provides an opportunity to review the detailed history, physical examination, investigation reports and keep the child under close observation with an ongoing assessment to establish the cause of fever.

History

The history should include questions regarding characteristics of fever (onset, intensity, duration, frequency and pattern of fever). Intermittent fevers with a high spike and rapid defervescence suggest a pyogenic infection but can also be seen in tuberculosis, lymphoma, and connective tissue disorders. Remittent fevers are characterized by fluctuating peaks and a baseline that does not return to normal and are seen most commonly with viral infections, some bacterial infections (especially endocarditis), sarcoidosis, lymphoma, and atrial myxoma. Sustained fevers persist with little or no fluctuation but can appear to be intermittent if antipyretic agents are administered and are usually seen in enteric fever, typhus, brucellosis, etc. Hodgkin disease has a typical *Pel-Ebstein* type of fever (3–10 day cycles of febrile and afebrile periods). Fever with chills and rigors suggest malaria, urinary tract infection,

Table 1 Common causes of fever of unknown origin (FUO) in children

1. <i>Infections</i>
<i>Bacterial:</i> Tuberculosis, typhoid, paratyphoid, brucellosis, listeriosis, meningococcemia, yersiniosis, <i>Campylobacter</i> , relapsing fever, Lyme disease
<i>Viral:</i> Infectious mononucleosis (Epstein-Barr-virus), human immunodeficiency virus (HIV)/AIDS, hepatitis, and cytomegalovirus (CMV) disease
<i>Parasitic:</i> Malaria, kala-azar, amebic abscess, hepatic amebiasis, giardiasis, toxoplasmosis, trypanosomiasis, and visceral larva migrans
<i>Rickettsia:</i> Scrub typhus, Q fever, Rocky mountain spotted fever
<i>Fungal:</i> Disseminated candidiasis, histoplasmosis, aspergillosis, blastomycosis, disseminated coccidioidomycosis, and cryptococcosis
2. <i>Connective tissue and autoimmune disorders:</i> Systemic lupus erythematosus (SLE), juvenile idiopathic arthritis (JIA), rheumatic fever, juvenile dermatomyositis, chronic active hepatitis, polyarteritis nodosa, mixed connective tissue disorder, Behçet disease, and autoimmune thyroiditis
3. <i>Hypersensitivity disorders:</i> Drug fever, serum sickness, hypersensitivity pneumonitis, and Weber-Christian disease
4. <i>Malignancies:</i> Hodgkin disease, leukemia, lymphoma, inflammatory pseudotumors, pheochromocytoma, neuroblastoma, and Wilms tumor
5. <i>Granulomatous disorders:</i> Sarcoidosis, granulomatous hepatitis, inflammatory bowel disease
6. <i>Familial and hereditary syndromes:</i> Familial dysautonomia, familial Mediterranean fever, anhidrotic ectodermal dysplasia, Ichthyosis, and hypertriglyceridemia
7. <i>Hematologic causes:</i> Hemophagocytic lymphohistiocytosis syndromes, cyclic neutropenias, immunodeficiency states, Kikuchi-Fujimoto disease, and Castleman disease
8. <i>Endocrine causes:</i> Addison disease, thyrotoxicosis, hypothalamic central fever, and diabetes insipidus
9. <i>Miscellaneous causes:</i> Factitious fevers, infantile cortical hyperostosis, pancreatitis, drug fevers, poisonings, thrombophlebitis, and pulmonary embolism

abscesses or nosocomial infections. Relapsing fever with periods during which patients are afebrile for one or more days between febrile episodes may be seen with malaria, rat-bite fever, *Borrelia* infection, and lymphoma.

The clinician needs to enquire about the way temperature was assessed-perceived manually or documented by a thermometer along with the site of documentation; localizing symptoms of fever; recent exposures like vaccination or animal/insect bites or receipt of any blood transfusion or biological products; exposure to a family member with fever or any infectious disease, past history of any significant illnesses such as tuberculosis, urinary infections, congenital heart disease, any surgical procedure; any history of travel in the recent past to specific disease endemic areas, history of exposure to any heavy metals or poisonous fumes and history of an underlying chronic disease and medication history. History of recurrent episodes of fever may give a clue to certain cyclic causes of fever, e.g., cyclic neutropenia, and may also be seen in immunodeficiency disorders, hyperimmunoglobulin D disease and central nervous system disorders of temperature regulation. Tick bites can lead to Rocky Mountain spotted fever, ehrlichiosis, tularemia, tick-borne relapsing fever, or Lyme disease. Ingestion of raw meat or raw shellfish may lead to brucellosis, toxoplasmosis, tularemia, or hepatitis. Familial Mediterranean fever is generally seen in Jewish, Turkish, and Arab populations. Familial dysautonomia is common in Ashkenazi Jews.

Examination

A detailed clinical examination, which needs to be repeated frequently, so as not to miss any subtle or evolving signs, remains the most important clinical tool for diagnosis. While examining the child, particular attention should be paid to evaluation of skin, fundus, throat, lymph nodes, genitalia and sinuses. Detailed eye inspection including that of cornea, conjunctiva, orbit, uveal tract and retina may point towards many infectious, collagen vascular, malignant or metabolic disorders. Absence of sweating during fever may be noted in anhidrotic ectodermal dysplasia and absence of malaise or other generalized signs in a child with a history of prolonged high fevers can signal factitious fever. Careful rectal, external genitalia, and pelvic examination (where indicated) should be performed.

Laboratory Tests

The laboratory and imaging evaluations for FUO should be directed toward the likely causes of fever based upon the patient's age, duration of fever, history and findings from the physical examination. Appropriate laboratory investigations such as complete blood counts with total leukocyte count, differential leukocyte count, erythrocyte sedimentation rate (ESR), peripheral blood smear examination for malaria and filariasis (night blood) are routinely performed. **Table 2** lists the various hematological abnormalities which may be an indicator of a specific disease condition. An elevated ESR more than 30 mm/hour suggests inflammation. ESR and C reactive protein (CRP) though nonspecific, can serve as prognostic markers and be used for monitoring purposes. Simple serological tests for typhoid, brucellosis, leishmaniasis, toxoplasmosis and amebiasis, and bacteriological culture of blood for *Salmonella* and *Brucella* should be undertaken.

Repeated microscopic examination and cultures of blood, urine, throat, sputum, and stool for bacterial and fungal infections should be carried out at periodic intervals. Sterile pyuria can be a clue to Kawasaki disease or genitourinary tuberculosis. Serum electrolytes, blood urea nitrogen (BUN), creatinine, and

Table 2 Hematologic clues to specific disease states

Anemia	Malaria, Infective endocarditis, Inflammatory bowel disease, systemic lupus erythematosus, tuberculosis, etc.
Thrombocytosis	Kawasaki disease
Total white blood cell count >10,000/mm ³	Serious bacterial infection
Nonsegmented polymorphonuclear leukocytes > 500/mm ³	Serious bacterial infection
Eosinophilia	Parasitic, fungal, allergic or immunodeficiency states
Immature band forms	Leukemia
Activated lymphocytes	Viral Infection

hepatic enzymes are obtained to evaluate renal and/or hepatic involvement. Hypernatremia may be seen in diabetes insipidus, elevated hepatic enzymes may be a clue to a viral infection.

Bone marrow examination can help in diagnosing leukemia, lymphoma, histiocytic disorders, and hemophagocytic syndromes. If specifically indicated, cultures of bone marrow, cerebrospinal fluid, gastric aspirate, lymph node aspirate and liver aspirate for aerobic and anaerobic bacteria, mycobacteria and fungi may prove to be invaluable. Serum antinuclear antibody should be obtained for children with a strong family history of rheumatic disease. Serum concentrations of immunoglobulins (IgG, IgA, and IgM) should be measured in children with evidence of recurrent or persistent fever and a negative initial evaluation. Hypogammaglobulinemia may indicate an immunodeficiency, while elevated levels may be seen in chronic infections, or autoimmune disorders. Serological tests should also be repeated to look for any rising antibody titers. Modern molecular diagnostic techniques; e.g., polymerase chain reaction (PCR) are now available for diagnosis of several infectious agents. A variety of immunological tests for detection of various autoantibodies is now available to rule out various autoimmune disorders.

Diagnostic imaging of the nasal sinuses, mastoids, chest and gastrointestinal (GI) tract by radiography, barium studies, ultrasonography, computerized tomographic (CT) scans and magnetic resonance imaging (MRI) as indicated, should initially be performed for specific indications, but may be done in children in whom FUO persists without a cause being established. Endoscopic evaluation of respiratory, genitourinary and gastrointestinal tract may help positron emission tomography (PET) scanning and immunoscintigraphy may be helpful in patients with persistent FUO who remain without a diagnosis after initial evaluation. Lymphangiography can be resorted to, for demonstrating retroperitoneal, iliac and periaortic lymph nodes. Biopsy (e.g., of lymph nodes, bone marrow or liver) should be reserved only for children with evidence of involvement of specific organs. If indicated, skin, pleura, muscle, kidneys, etc. can also be biopsied.

MANAGEMENT

Empirical treatment with anti-inflammatory agents (except for symptomatic relief in suspected JIA) or antibiotics should be avoided as they may mask the diagnosis or alter the course of certain conditions like infective endocarditis, meningitis or osteomyelitis and may also interfere with isolation of certain microorganisms on cultures. Disease specific appropriate interventions should be initiated soon after establishing the diagnosis.

IN A NUTSHELL

1. Fever of unknown origin (FUO) is defined as fever (rectal temperature $> 38^{\circ}\text{C}$) documented by a health-care personnel, for which no cause is identifiable after 3 weeks of outpatient evaluation and after 1 week of evaluation as an inpatient.
2. A detailed clinical history and examination, repeated frequently, is crucial for diagnosis of FUO.
3. Infectious diseases, connective tissue diseases and autoimmune disorders are the most common causes of FUO in children.
4. Children with FUO generally do not need an emergency assessment or empirical anti-inflammatory agents and/or antibiotics.

Chapter 29.1

Natural History of Bacterial Infection

VG Ramachandran, Piyush Gupta

KOCH'S POSTULATES

It may not be very easy to show that a specific bacterial species is the cause of a particular disease. Robert Koch (1884) proposed a set of postulates, which are applied broadly to link specific bacterial species with specific diseases (**Box 1**).

BOX 1 Koch's postulates

- The microbial pathogen should be present in all cases of the disease in question, and its distribution should be in accordance with the lesions observed in the body
- The microorganism should be grown in pure culture *in vitro* or outside the body of the host for several generations
- When a pure culture of the microorganism is inoculated into susceptible animal species, the typical disease must result
- The microorganism must again be isolated from the lesions of such experimentally produced disease.

Koch's postulates permit the bacteria to be classified as pathogens, opportunistic pathogens or nonpathogens. Some bacterial species are always considered to be pathogens and their presence is abnormal, e.g., *Mycobacterium tuberculosis* and *Yersinia pestis*. These bacteria readily fulfill Koch's postulates. Some bacterial species are part of the normal flora of humans and animals but may also frequently cause disease—*E. coli* is a part of the gut flora in humans, but it is also a common cause for urinary tract infections. Other bacteria only cause disease in immunosuppressed or immunocompromised persons and are *opportunistic pathogens* (e.g., *Pseudomonas*).

However, there are many pathogenic microorganisms which fail to meet one or the other criteria of these postulates. Agents of syphilis (*Treponema pallidum*) and leprosy (*Mycobacterium leprae*) have not been grown *in vitro*; but there are animal models of infection with these agents. The agent of gonorrhea (*Neisseria gonorrhoeae*) is readily cultivable in the laboratory though there is no animal model of infection. Nonetheless, experimental infection in humans has been produced which substitutes for an animal model.

TRANSMISSION OF INFECTION

Some bacteria that commonly cause human disease primarily exist in animals and incidentally infect humans, e.g., *Salmonella* species infect animals and are transmitted to humans through meat and meat products. Certain bacteria do not involve humans in their normal life cycle, and, therefore, they are not adapted to

the human body. This results in the outbreak of a severe form of the disease. *Yersinia pestis*, the agent of plague has an established life cycle in rodent and rodent fleas, and its transmission by the fleas to humans is inadvertent. The *Clostridium* species are ubiquitous in the soil and are transmitted to humans by ingestion (*C. perfringens* gastroenteritis and *C. botulinum* food-poisoning) or by contamination of wounds with soil (*C. perfringens* gas gangrene and *C. tetani* tetanus).

The symptoms of diseases (i.e., rhinorrhea, diarrhea, genital discharge) caused by microorganisms often promote transmission of the agents. *Vibrio cholerae* can cause copious diarrhea, which may contaminate river or drinking water. Ingestion of these can subsequently result in infection and disease.

THE INFECTIOUS PROCESS

The bacteria lodge themselves in or on a host, and set about establishing a primary site of infection. Subsequently, they multiply and spread through tissues or lymphatic system to the bloodstream, leading to bacteremia, which can be transient or persistent. Hematogenous route disseminates bacteria widely in the body and transports them selectively to tissues suitable for their growth.

Streptococcus pneumoniae are normally present in the nasopharynx of 5–40% of the healthy population. Occasionally these may get aspirated into the lungs and cause infection in the terminal air spaces of the lungs. Multiplication of the pneumococci and resultant inflammation lead to pneumonia. The pneumococci enter the lymphatics of the lungs and move to the bloodstream. Bacteremia is present in only 10–20% of persons with pneumococcal pneumonia. Following bacteremia, pneumococci can spread to secondary sites of infections, e.g., cerebrospinal fluid, joint spaces and heart valves resulting in meningitis, septic arthritis and endocarditis, respectively.

The infectious process in cholera involves ingestion of *V. cholerae* (VC), chemotactic attraction of the bacteria to the gut epithelium, motility of the bacteria by a single polar flagellum, and penetration of the mucus layer on the intestinal surface. The *V. cholerae*'s adherence to the epithelial cell surface is mediated by pili. The cholera toxin produced leads to the inflow of chloride and water into the lumen of the gut causing diarrhea and electrolyte imbalance.

BACTERIAL VIRULENCE FACTORS

Many factors determine the bacterial virulence or ability to cause infection and disease. These include the adherence factors, ability to invade the host and produce toxin, and presence of various tissue-degrading enzymes, peptidoglycans, IgA proteases, anti-phagocytic factors, intracellular pathogenicity and antigenic heterogeneity. Some of these factors are discussed below:

Adherence factors Once bacteria enter the body of the host, they must adhere to cells of a tissue surface; otherwise they would be swept away by mucus and other body fluids. The interactions between bacteria and tissue cell surface in the adhesion process

are complex, and several factors are involved. Bacteria and the host cell commonly have negative surface charges, i.e., repulsive electrostatic forces, which are overcome by hydrophobic interaction between the two cells. The more hydrophobic the bacterial cell surface, the greater is the adherence to the host cells; different strains of bacteria within a species may vary widely in their hydrophobic capability.

Bacteria also have specific surface molecules that interact with host cells. Pili are hair-like appendages that extend from the bacterial cell surfaces. The *E. coli* that cause diarrhea have pili mediating adherence to intestinal epithelial cells. Group A streptococci and *Streptococcus pneumoniae* also have hair-like appendages termed fibrillae, that extend from their cell surfaces. The cell wall's lipoteichoic acid causes adherence of the streptococci to buccal epithelial cells; M-protein acts as an antiphagocytic molecule. Certain bacteria employ other specific ligand-receptor mechanisms to promote bacterial adherence to host cells.

Invasion of host cells and tissues Invasion is the term commonly used to describe the entry of bacteria into the host cells, implying an active role for the organisms and a passive role for the host cells. In many infections, the bacteria produce virulence factors that influence the host cell, causing them to engulf the bacteria. The host cells also play a very active role in this process.

Invasion of the host epithelium is central to the infectious process of some bacteria, e.g., *Salmonella*, *Yersinia* and *Chlamydiae*. Once inside the host cell, bacteria may remain enclosed in a vacuole or be dispersed in the cytoplasm. Some bacteria such as shigellae multiply within the host cells.

Shigella species adhere to host cells in vitro. The adherence induces the formation of pseudopods by the host cells, which engulf the bacteria. At least three proteins (invasion plasmid antigens: Ipa—Ipa B, Ipa C and Ipa D) contribute to the process. Once inside the host cells, the shigellae are either released or escape from the phagocytic vesicle and multiply in the cytoplasm. The pathogenesis of *Shigella* adherence and invasion in vivo appears to be different. After adhering to the surface of M-cells in Peyer's patches, shigellae are phagocytosed and escape killing by the macrophages. Further spread to adjacent cells occurs in a similar manner.

Neisseria gonorrhoeae use pili as primary adhesins and opacity associated protein (Opa) as secondary adhesins to enter host cells. Certain Opa proteins mediate adherence to polymorphonuclear cells. Some gonococci survive after phagocytosis by these cells. Pili and Opa together enhance the invasion of cells cultured in vitro. Further intracellular multiplication and migration to sub-epithelial space occurs by an unknown mechanism.

TOXINS

Toxin production and other virulence properties are generally independent of the ability of the bacteria to invade cells and tissues. Toxins are generally classified into two groups: endotoxins and exotoxins.

Endotoxins

These are integral parts of the cell wall of *gram-negative* bacteria and are released on bacterial death and in part during their growth. They do not necessarily need to be released to have biological activity. Endotoxins are stable lipopolysaccharide complexes and can withstand temperatures above 60°C for hours without loss of toxicity. These are weakly antigenic and may produce protective antitoxic antibodies. However, protective relationship between antibody titers and protection from disease is less clear than with exotoxins.

Endotoxins are moderately toxic and very high doses are fatal. These cannot be converted into toxoids. They usually produce fever

in the host by the release of interleukin-1 and other mediators. Some of the clinical conditions where endotoxins are implicated include septic shock, fulminant hepatic failure, cirrhosis, obstructive jaundice, inflammatory bowel disease, acute renal failure, acute respiratory distress syndrome, major abdominal trauma, neonatal necrotizing enterocolitis, radiation injury, graft versus host disease and toxic shock syndrome. Endotoxins in the bloodstream are initially bound to circulating proteins, which then interact with receptors on macrophages and monocytes and other cells of the reticuloendothelial system. Interleukin-1, tumor necrosis factor and other cytokines are released and the complement and coagulation cascades are activated. This results in fever, leucopenia, hypotension and shock due to impaired perfusion of essential organs such as brain, kidney and heart. The end result is massive organ dysfunction and death.

Exotoxins

Exotoxins are produced by both, living *gram-positive* and *gram-negative* bacteria. These are relatively unstable polypeptides and their toxicity gets rapidly destroyed at temperatures above 60°C. They are highly immunogenic and stimulate formation of high titer antitoxin. Antitoxin can completely neutralize toxin. Exotoxins, though highly toxic, can be converted to antigenic nontoxic *toxoids* by heat and formalin. They are used for immunization purposes (e.g., diphtheria toxoid). Release of exotoxin in the host usually does not produce fever.

Some of these toxins have had major roles in world history—tetanus caused by the exotoxin of *Clostridium tetani* killed as many as 50,000 soldiers during the Second World War. Vaccines called toxoids have been developed for some of the exotoxin mediated diseases, and continue to be important in the prevention of disease. Many exotoxins consist of A and B subunits. The A subunit provides the toxin activity and the B subunit generally mediates adherence of the toxin complex to the host cell and aids its entry into it. Cited below are few examples of exotoxins and their effects.

C. diphtheriae It is a gram-positive bacillus which produces diphtheria toxin causing diphtheria. It affects the heart, kidney, liver and adrenals and can be lethal in a dose of 0.1 mg/kg.

Clostridium tetani It is an anaerobic gram-positive bacillus that causes tetanus. This bacillus, present in the environment, contaminates the wound, and its spores germinate in the anaerobic environment of the devitalized tissue; infection often is minor and not clinically apparent. The vegetative forms of *Clostridium tetani* produce the toxin *tetanospasmin*, which has two peptides (Mr 50,000 + Mr 1,00,000)—the larger peptide binds to gangliosides, the smaller peptides appear to have toxic activity. Tetanospasmin reaches the central nervous system by retrograde transport along axons and through the systemic circulation. It blocks the release of an inhibitory mediator in the nerve endings resulting in generalized muscle spasms. Extremely small amount can be lethal for humans. Tetanus is totally preventable in immunologically normal people by immunization with tetanus toxoid.

Clostridium botulinum (CB) It causes botulism. CB is found in soil or water and may grow in canned vacuum packed foods. It produces the most potent toxin known on earth; it is heat labile. The toxin is absorbed from the gut and carried to motor nerves where it blocks the release of acetylcholine at the neuromuscular junctions resulting in flaccid paralysis.

Clostridium perfringens (*syn C. Welchii*) It causes gas gangrene. Its spores enter the wound when contaminated with soil or feces. In the presence of necrotic tissue, they germinate and produce several histiocytic and membrane damaging toxins. Many of these are lethal, cytolytic and necrotizing, and favor the spread of gas gangrene.

Staphylococcus aureus (SA) It grows on mucous membranes or in wounds and may liberate toxin-1 (TSST-1) which causes toxic shock syndrome (TSS). The illness is characterized by shock, high fever, a diffuse red rash that later desquamates with multiple system involvement. Toxic shock syndrome also occurs during immunization sessions where measles vaccines are contaminated with SA. *S. aureus* also produces an epidermolytic toxin that acts on stratum granulosum of the epidermis and results in scalded skin syndrome. Other toxins liberated are α , β , γ , δ , hemolytic toxins— α toxin has a cytotoxic role and is responsible for wound infections and septicemia.

Enterotoxins

Exotoxins associated with diarrheal illnesses and food poisoning are called enterotoxins. A list of these toxins and their mode of action along with the diseases produced by them is given in **Table 1**.

Table 1 Bacterial toxins that affect the intestine (enterotoxins)

Organism	Disease	Toxin	Mode of action
<i>Vibrio cholerae</i>	Cholera	Cholera toxin	Activation of adenylate cyclase and elevation of intracellular AMP
<i>Shigella dysenteriae</i>	Dysentery	Shiga toxin	Enterotoxic, cytotoxic and neurotoxic inhibits protein synthesis
Enteropathogenic <i>E. coli</i> (EPEC)	Diarrhea	Low levels of shiga like toxin, (SLT-1 and SLT-2)	Enterotoxic, cytotoxic, neurotoxic antigenically related but not identical to Shiga toxin
Enteroinvasive <i>E. coli</i> (EIEC)	Dysentery like illness	Multiple SLTs	
Enterohemorrhagic <i>E. coli</i> (EHEC)	Hemorrhagic colitis, hemolytic uremic syndrome, voluminous diarrhea	High level of SLT	
Enterotoxigenic <i>E. coli</i> (ETEC)	Diarrhea	Heat-labile toxin Heat-stable toxin	Related to cholera toxin, activates adenylate cyclase Short peptide, nonantigenic, activate particulate fraction of guanylate cyclase leading to elevation of cyclic GMP
<i>Bacillus cereus</i>	Food-poisoning with vomiting and diarrhea	Diarrheagenic toxin/lethal toxin	Precise basis of toxin action at cellular level not known, causes fluid accumulation, increased vascular permeability and necrosis
<i>Staphylococcus aureus</i>	Food-poisoning with vomiting	Seven types of enterotoxin, A, B, C1, C2, C3, D, E	Molecular basis not known, causes fluid imbalance in colon. Believed to stimulate vomiting center through vagus nerve. Also causes systemic effects
<i>Clostridium difficile</i>	Pseudomembranous colitis	Toxin A	Enterotoxic, lethal; causes fluid accumulation and hemolytic diarrhea
<i>Clostridium perfringens</i>	Food-poisoning with diarrhea	Toxin B Cytotoxic, enterotoxin	Lethal, acts intracellularly Cytotoxic damage to intestinal epithelial cells

Chapter 29.2

Principles of Antibiotic Therapy

Anita Shet

Antimicrobial agents include some of the most widely used therapeutic agents worldwide. The terms antibiotic, antimicrobial and anti-infective agents are often used interchangeably, and encompass a wide variety of pharmaceutical agents that include antibacterial, antifungal, antiviral and antiparasitic drugs. Among these agents, antibacterial agents are the most common, and are a focus of this chapter. A child, who develops features suggestive of an infection, requires a physician who must first determine whether the infection is likely to be caused by an organism that is susceptible to antimicrobial therapy. The selection of optimal antibiotic therapy for the child is based on the assessment of need, benefits, costs and risk of the specific therapy for each child. Inappropriate selection of antibiotic therapy subjects the child to unnecessary toxicities, possible risk of drug-resistant bacterial infection, erroneous diagnosis and needless costs to the individual and to the society.

Evidence-based guidelines are available and can be used for many situations that call for targeted therapy for specific infectious diseases where the specific microorganisms are known or assumed. However, these guidelines should be applied in the context of host characteristics, cost and availability of therapy, and response to therapy. This chapter presents general principles that guide appropriate use of antibiotic therapy that benefit the individual child and family as well as society.

SELECTION OF AN OPTIMAL ANTIBIOTIC REGIMEN

There are several steps toward selecting an optimal antibiotic regimen. These steps must be sequentially addressed in order to select the best possible therapy that will bring the maximum benefit to the child.

1. Predicting the Pathogen

The first step in selecting a suitable antibiotic is establishing the infectious disease diagnosis. One needs to define the site of infection and the host status. Knowledge that certain species of bacteria have a predilection for certain tissues is essential. For example, *Neisseria meningitidis*, group B streptococci and *Streptococcus pneumoniae* are likely to infect the central nervous system and cause meningitis, while *Staphylococcus aureus* and *Streptococcus pyogenes* have a proclivity for skin and bone infections. One may also eliminate certain pathogens based on the site of infection; for instance, in uncomplicated urinary tract infections, *Staphylococcus aureus* may be dismissed as a likely pathogen.

2. Considering Age of the Child

The age of the child can often predict the bacterial pathogen; group A *Streptococcus*, *Listeria monocytogenes* and *Escherichia coli* are the most likely pathogens in meningitis in infants in the first 3 months of age, while *Streptococcus pyogenes* from school-related exposure is more common in older children. *Staphylococcus aureus* as a cause for severe pneumonia is more likely to be thought of in preschool children rather than those above 6 years of age.

3. Factoring in Host Status

Infecting pathogens are predictable if the child is healthy, has intact immunity and normal barriers to infection. If the child has

an underlying T-cell or B-cell lymphocyte defect, bacteria that are not normally pathogenic can also cause infection. In predicting possible pathogens, host factors that need to be considered include trauma to skin or mucous membranes, presence of a foreign body, a recent surgical procedure, an indwelling medical device or presence of immunosuppressive agents.

4. Ascertaining a Medical and Microbiological Diagnosis

Maximum efforts should be made to arrive at a diagnosis of the infectious disease syndrome, derive the etiology of the infection, and obtain a microbiological isolate for accurate diagnosis and susceptibility testing. The power of the Gram stain (and other appropriate stains) along with simple microscopy should never be underestimated. In addition, bacterial cultures and susceptibility tests should be obtained whenever possible. Rapid diagnostic tests, such as latex agglutination tests for *Streptococcus pneumoniae*, also have a place in diagnosis, although the sensitivity and specificity of these tests may need improvement. Molecular techniques are emerging as diagnostic modalities, which, when done meticulously, have a useful place in the diagnosis of the infection and appropriate antibiotic selection.

5. Testing Antibiotic Susceptibilities

There may be wide variation in the antibiotic susceptibility patterns in different areas, even when the organisms are similar. For instance, in a single geographic area, it is possible that an *E. coli* isolate from a urinary tract infection in a child previously unexposed to antibiotics will have a different susceptibility pattern from an *E. coli* isolate from a child undergoing several chemotherapy cycles for leukemia, and versus a similar isolate from preterm infant in an intensive care unit. Geographic variations may also be due to differing patterns of antibiotic use in these areas. A hospital antibiogram is a useful tool in selecting antibiotics for different infections, as the susceptibility patterns reflect the local trends prevailing in that region. The probability that the selected antibiotic will be effective against the presumed bacterial pathogen is directly related to the proportion of infected pathogens infecting patients in that location. The susceptibility of a specific bacterial pathogen to an antimicrobial agent can be measured in the laboratory by defining the lowest concentration of the antibiotic that can inhibit the growth of the pathogen, the minimum inhibitory concentration (MIC), measured in µg/mL.

6. Considering Specific Properties of the Antibiotic

The selection of the antimicrobial agent is guided by specific properties of the drug, particularly the administration route, absorption, the tissue distribution of the antibiotic at the site of infection, and drug elimination characteristics.

Pharmacodynamics

Understanding pharmacodynamics of antimicrobials is important in predicting microbiologic and clinical success of antibiotic treatment. The antibiotic effect is related directly to either the concentration attained at the site of infection or the time during which an effective concentration of the antibiotic is present at the site of infection. Aminoglycosides and fluoroquinolones exhibit *concentration-dependent killing* indicating that higher concentrations of the drug result in more rapid killing. These antibiotics also exhibit a prolonged antibiotic effect even after the serum level decreases below the MIC for the particular organism. Thus, higher doses and often once-daily doses result in greater efficacy.

Beta-lactam antibiotics, erythromycin, clindamycin, vancomycin and linezolid demonstrate *time-dependent killing*, where

optimal activity is related to the time during which the antibiotic concentration remains above the MIC at the site of infection. For these antibiotics, having greater antibiotic concentrations at the site of infection would not achieve a greater inhibitory effect. These agents also exhibit a postantibiotic effect, where bacterial growth is inhibited for a substantial time after exposure to the antibiotic.

Pharmacokinetics

Pharmacokinetics includes the absorption, concentration, distribution, metabolism and excretion of the antibiotic, and these parameters can vary widely in children based on age, other host factors and illness severity. The volume of distribution of antibiotics varies profoundly during the first few years of life, and is greater in the neonate compared to the infant. Drug elimination is low at birth, peaks in infancy and then reaches adult values gradually in later childhood. Thus, the dose of antibiotics needs adjustment during different ages, in order to maintain efficacy and minimize toxicity.

Specific concentrations of antibiotics may vary in tissues and organs, and different body compartments can have widely differing antibiotic elimination half-lives. The route of administration plays a role in optimal efficacy. In general, most parenteral antibiotics result in higher serum concentrations than when given orally. Selecting the most appropriate antibiotic dose, when switching from intravenous to oral therapy, depends most on the absorption characteristics of the oral agent. Oral bioavailability is fair for most beta-lactam antibiotics; serum concentrations are only 5–10% of those obtained when beta-lactam antibiotics are given parenterally. On the other hand, quinolones have excellent bioavailability; serum concentrations after an oral dose are close to that found after an intravenous dose.

7. Selecting Empiric vs. Definitive Antimicrobial Therapy

When an infection is identified, empiric therapy is instituted based on the presumed pathogen, local resistance patterns and the risk of severity of the infection. In general, with increasing severity of infection in the child, the need to start antibiotics with appropriately broad antibacterial activity at the highest tolerated dose as empiric therapy becomes increasingly urgent.

Broad-spectrum Therapy

In critically ill patients, broad-spectrum antibiotics such as beta-lactam/beta-lactamase inhibitor combinations such as co-amoxiclavulanic acid and piperacillin-tazobactam, third generation cephalosporins, quinolones, and carbapenems, are useful for initial empiric therapy. These antibiotics cover a greater range of pathogens and should be switched to more targeted therapy once the offending pathogen has been identified. Prolonged or extensive use of broad-spectrum agents can lead to selection of drug resistant bacteria, fungal infections and antibiotic-associated diarrhea.

Narrow-spectrum Therapy

Whenever possible, it is preferable to use narrow spectrum agents such as penicillin, trimethoprim, erythromycin and cloxacillin. Once the pathogen is identified, a narrow-spectrum agent can provide the same degree of bacterial eradication and clinical efficacy with decreased toxicity, decreased drug resistance risk and decreased costs. An example is the treatment of ventilator-associated pneumonia; initial empiric treatment with a carbapenem agent can be narrowed to more targeted therapy with cefotaxime if susceptible *Klebsiella* species is isolated.

8. Considering Antibiotic Efficacy at the Site of the Infection

The capacity of the selected antibiotics to achieve a concentration equal to or greater than the MIC at the site of infection plays a critical role in maintaining the efficacy of the regimen. At certain body compartments, such as cerebrospinal fluid, bone, middle ear compartment and abscess cavities, the antimicrobial concentration achieved may be several times lower than the serum level of the antimicrobial agent. Examples include macrolides and first- and second-generation cephalosporins that do not cross the blood-brain barrier, and hence are not recommended for central nervous system infections. Aminoglycosides are less active in the acidic, low-oxygen milieu of abscess cavities, and hence are less efficacious antimicrobial agents in such settings, unless there is complete drainage of the abscess. Variations within the same class of antibiotics also exist; moxifloxacin achieves poor concentration in the urine due to its low renal excretion, while ciprofloxacin achieves good concentrations and works well against urinary infections caused by susceptible bacteria. Clindamycin and fluoroquinolones achieve good tissue concentrations in bone and are excellent agents for bone and joint infections.

9. Deciding the Duration of Antibiotic Therapy

Factors that determine the optimal duration of therapy depend on the severity of the infection, virulence of the infecting pathogen, susceptibility to the antimicrobial agent used, penetration of the antibiotic at the site of infection, and host factors that may impair antimicrobial activity. Longer treatment courses may be recommended for resistant organisms or immunocompromised hosts. For most infections, a recommendation for duration of therapy is based on the best available evidence for that particular childhood infection, together with experience and consensus. For example, the recommended duration of treatment in childhood meningitis varies according to the infecting organism as follows: *Neisseria meningitidis*, (5–7 days); *Streptococcus pneumoniae* (10–14 days); Gram-negative enteric bacilli (21 days).

10. Therapeutic Drug Monitoring

The therapeutic index of an antibiotic is the ratio of its toxic dose to its therapeutic dose. Most antimicrobial agents have a wide therapeutic index, and allow standard doses to be used, except when adjustments have to be made for age, renal or hepatic function. Some antibiotics such as aminoglycosides and vancomycin that demonstrate toxicity at high doses require monitoring of serum levels due to their narrow therapeutic index.

Table 1 provides a classification of antibiotics, resistance mechanisms and spectrum of activity. Reasons why a particularly prescribed antibiotic does not work are listed in **Box 1**.

BOX 1 Why is my antibiotic not working?

- Incorrect dose of antibiotic
- Incorrect choice of antibiotic
- Wrong organism—viruses
- Not reaching site of infection (deep abscess)
- Defective immune system
- Drug fever.

ANTIMICROBIAL PROPHYLAXIS

Appropriate prophylactic antimicrobial use in a patient is governed by the following principles; a high risk of infection is present in the patient, the degree and duration of risk can be estimated, and the likely offending organisms and their susceptibility patterns are known. Prophylaxis may be short- or long-term.

Table 1 Classification of antibiotics, resistance mechanisms and spectrum of activity

Antibiotic class	Antibiotic examples	Spectrum of activity	Mechanism of resistance
Beta-lactam antibiotics			
Natural penicillins	Benzyl penicillin, Penicillin V	Gram-positive: Streptococci, pneumococci, <i>Enterococcus</i> species Gram-negative: <i>Neisseria</i> species, <i>Treponema pallidum</i> , <i>Leptospira</i> species Anaerobes	• Beta-lactamase production, including extended-spectrum beta-lactamase (ESBL) and carbapenemase
Semisynthetic penicillin	Cloxacillin	Gram-positive: As above, and <i>Staphylococcus aureus</i> (except MRSA)	• Altered penicillin-binding proteins
Aminobenzyl penicillin	Ampicillin, Amoxicillin	Gram-positive: As above Gram-negative: <i>E. coli</i> , <i>H. influenzae</i> , <i>Neisseria</i> species	
Ureidopenicillin	Piperacillin	Gram-positive: As above Extended Gram-negative coverage: <i>Proteus</i> , <i>Pseudomonas</i> , <i>Enterobacter</i> species	
Beta-lactase inhibitor combinations	Ampicillin/sulbactam, Amoxicillin/clavulanate, Piperacillin/tazobactam	Gram-positive: As above. <i>Staphylococcus aureus</i> (except MRSA), beta-lactamase producing strains. Extended Gram-negative and anaerobic coverage	
Cephalosporins			
First generation	Cefazolin, Cefalexin, Cefadroxil	Gram-positive: Streptococci, Pneumococci, <i>Enterococcus</i> species <i>Staphylococcus aureus</i> (except MRSA) Gram-negative: <i>E. coli</i>	
Second generation	Cefuroxime, Cefaclor, Cefoxitin, Cefotetan	Gram-positive: As above Gram-negative: Including enterobacteriaceae (<i>E. coli</i> , <i>Klebsiella</i> , <i>Proteus</i> , <i>Salmonella</i> , <i>Shigella</i> , etc.) Some anaerobes	
Third generation	Cefotaxime, Ceftriaxone, Ceftazidime, Cefixime, Cefpodoxime, Cefoperazone	Gram-positive: As above Extended Gram-negative: <i>Pseudomonas</i> , <i>Serratia</i> species Anaerobes	
Fourth generation	Cefepime	As above, including <i>Pseudomonas aeruginosa</i>	
Carbapenems			
	Imipenem, Meropenem, Ertapenem	Gram-positive: As with third generation cephalosporins above Extended Gram-negative: <i>Pseudomonas</i> , <i>Serratia</i> species Anaerobes	
Monobactams			
	Aztreonam	Gram-negative: <i>Citrobacter</i> , <i>Enterobacter</i> , <i>E. coli</i> , <i>Klebsiella</i> , <i>Pseudomonas</i> species	
Aminoglycosides			
	Streptomycin, Gentamicin, Amikacin	Gram-positive: <i>Staphylococcus aureus</i> (rare) Gram-negative: <i>E. coli</i> , <i>Klebsiella</i> , <i>Enterobacter</i> , <i>Serratia</i> , <i>Proteus</i> , <i>Citrobacter</i> , <i>Acinetobacter</i> , <i>Pseudomonas</i> species	• Enzymatic inactivation • Altered uptake • Efflux pump
Tetracyclines			
	Doxycycline, Minocycline	Gram-positive: <i>Actinomyces</i> species Gram-negative: <i>Vibrio cholerae</i> , <i>Brucella</i> , <i>Campylobacter</i> , <i>Yersinia</i> , <i>Neisseria</i> species Others: <i>Borrelia</i> , <i>Neisseria</i> species, <i>T. pallidum</i>	• Efflux pump
Glycylcyclines			
	Tigecycline	Gram-positive: Streptococci, Enterococci species (including vancomycin resistant species, <i>Staphylococcus aureus</i> (including MRSA)). Gram-negative: <i>Acinetobacter</i> , <i>Aeromonas</i> , <i>Citrobacter</i> , <i>Enterobacter</i> , <i>Klebsiella</i> , <i>Serratia</i> species Others: <i>Chlamydia</i> , <i>Mycoplasma</i> species	• Efflux pump
Quinolones			
	Norfloxacin	Gram-negative coverage	• Altered binding • Efflux pump
	Ciprofloxacin	Gram-positive: <i>Staphylococcus aureus</i> , streptococci species Gram-negative: <i>Aeromonas</i> , <i>Acinetobacter</i> , <i>E. coli</i> , <i>Klebsiella</i> , <i>Enterobacter</i> , <i>Citrobacter</i> , <i>Campylobacter</i> , <i>Proteus</i> , <i>Shigella</i> , <i>Salmonella</i> , <i>Pseudomonas</i> species.	
	Levofloxacin, Moxifloxacin	Gram-positive and negative: As above Anaerobes: <i>Clostridium perfringens</i> Others: <i>Mycoplasma</i> , <i>Legionella</i> species

Short-term prophylaxis A short course of antibiotics may be taken by close contacts of an ill patient in order to prevent transmission of the infection. For example, in bacterial meningitis, close contacts of the patient are advised a two-day course of rifampicin prophylaxis.

Long-term prophylaxis A postsplenectomy patient, who is under five years of age, should be advised to take penicillin twice daily, until completion of five years of age or for two years, whichever is later. Children with recurrent urinary tract infections, often as a result of anatomical abnormalities, such as vesicoureteral reflux, are prescribed long-term antibiotic prophylaxis with trimethoprim-sulfamethoxazole, nitrofurantoin or penicillins.

Surgical prophylaxis Antibiotics may be used to prevent infection during surgery. The appropriate antibiotic should be active against the pathogens most likely to contaminate the surgical site, and should be administered for the shortest effective period to minimize adverse effects, costs and drug resistance development. The type of surgery plays a crucial role in deciding about surgical prophylaxis. In many *clean* surgical procedures that are not associated with opening body cavities or inflamed tissue, such as simple facial surgery, antimicrobial prophylaxis is not indicated. On the other

hand, in *clean-contaminated* procedures that involve the opening of body cavities, or for *contaminated* procedures involving acute inflammation or visible wound contamination, antimicrobial prophylaxis is definitely indicated. For example, for percutaneous endoscopic gastrostomy (PEG) insertion, a single dose of first generation cephalosporin such as cefazolin, or alternatively, clindamycin is recommended. Similarly, for neurosurgical craniotomy or ventriculoperitoneal shunting procedures, a single dose of cefazolin or clindamycin is recommended.

Sites of action for major antibiotics are given in **Figure 1**.

ANTIMICROBIAL COMBINATIONS

Improved anti-infective efficacy is often achieved with combination of other drugs or antimicrobials. Clinical benefit of combination therapy may be achieved in the following ways:

Prevention of Emergence of Resistance

In the treatment of *Mycobacterium tuberculosis* infections, the use of two or more active agents can reduce the probability of resistant organisms developing. In invasive pseudomonal infections, the

Abbreviations: PABA, para-aminobenzoic acid, DHF, dihydrofolate, THF, tetrahydrofolate.

(Adapted from Neu HC, *Science* 1992;257:1064-1073; with additional inputs from Hancock RE, *Lancet Infect Dis*, 2005 Apr;5(4):209-18.)

use of a single agent, such as a beta-lactam, or aminoglycoside alone may be associated with emergence of resistant strains, and hence dual-combination therapy is recommended.

Inhibition of beta-lactamases

Certain bacteria, such as *Staphylococcal* species secrete beta-lactamases, enzymes that inactivate beta-lactam agents such as penicillin or amoxicillin. The coadministration of a beta-lactam inhibiting agent, such as clavulanic acid or tazobactam protects the antibiotic from degradation, thus retaining efficacy and also extending the spectrum of activity of the original antibiotic.

Synergy

Synergism occurs when the combined effect of two or more drugs is significantly greater than the independent effects of the drugs when used individually. The combination of a sulfonamide with a dihydrofolate reductase inhibitor such as trimethoprim is an example of synergy brought about by inhibition of consecutive steps in the folic acid pathway, that results in reduced MIC and enhancement of the combination antimicrobial's bactericidal activity. Another example is streptogramin antibiotics (quinupristin-dalfopristin) that act in concert on bacterial ribosomes, resulting in antibacterial activity when co-administered. Synergism can also occur when cell wall-active agents are used in conjunction with ribosomal-active agents. A beta-lactam antibiotic that acts on the cell wall can enhance the entry of an aminoglycoside, thus producing bactericidal synergy against certain organisms. This type of synergy is seen with enterococci, staphylococci, viridans streptococci and *Pseudomonas* species. For instance, in enterococcal endocarditis, penicillin in combination with gentamicin results in much higher clinical cure rates than when penicillin is used alone.

Alteration of Pharmacokinetics

A mechanism that increases levels or maintains high levels for a longer duration can also have a significant effect on the antimicrobial efficacy. A classic example is the addition of probenecid that has no intrinsic antimicrobial activity, yet delays renal excretion of penicillin, thus increasing the time above MIC at the site of infection. Cilastatin, in combination with imipenem, inhibits renal degradation of imipenem, and this increases its serum half-life and, therefore, efficacy.

ADVERSE REACTIONS TO ANTIMICROBIAL AGENTS

While prescribing any therapeutic agent, an important consideration is the presence of adverse effects related to the drug. Direct adverse effects may be a result of allergy, toxicity or drug-drug interactions (**Table 2**).

Allergic or hypersensitivity reactions usually constitute *immediate* (IgE-mediated) reactions. There may also be *delayed* reactions, often manifested as a skin rash. The most severe manifestation of IgE-mediated allergy is anaphylaxis. Elicited history for allergies is not very reliable; however, a negative skin test can reliably exclude the possibility of developing an IgE-mediated

Table 2 Classification of adverse effects of antibiotics

Direct
Allergic reactions
Toxicity
Drug-drug interaction
Indirect
Effects on commensal flora (<i>Clostridium difficile</i> infection)

reaction such as anaphylaxis and can help optimize antibiotic use. This method is often employed prior to prescription of parenteral penicillin.

Drug toxicity is usually associated with higher drug doses or prolonged use, and is particularly prominent when there is underlying organ dysfunction that results in impaired drug clearance. An example is nephrotoxicity associated with aminoglycosides. In vulnerable patients, the drug doses are often adjusted to minimize drug toxicity. Therapeutic drug level monitoring with dose adjustment during prolonged dosing schedules is a modality that may be used to ensure safe serum levels of the drug.

Drug interactions with concurrently administered drugs can increase or decrease serum levels and effects of the antimicrobial agent. Many such interactions are mediated via the cytochrome P450 enzyme system. For example, rifampicin is a powerful inducer of the cytochrome P450 enzymes, increasing metabolism and thus decreasing levels of concurrently prescribed drugs. Macrolides inhibit the cytochrome P450 enzymes, subsequently increasing levels of other drugs such as the prokinetic cisapride, resulting in a dangerous risk of cardiac arrhythmias. In addition, certain drug combinations can also cause additive toxicity, as shown by the concomitant use of amphotericin and gentamicin, which can significantly increase the risk of nephrotoxicity.

Indirect adverse effects include the inhibition of normal gastrointestinal bacterial commensals, resulting in the overgrowth of pathogens, leading to *Clostridium difficile* mediated diarrhea.

ANTIMICROBIAL RESISTANCE: MECHANISMS AND DETECTION (ALSO SEE CHAPTER 27.3)

What drives antimicrobial resistance? The widespread and often injudicious use of antimicrobial agents is an important cause of emergence of drug resistance in the hospital and community settings. Other factors include incorrect dosing, and poor adherence to prescribed antibiotics.

Mechanisms of Antimicrobial Resistance

Intrinsic resistance can be attributed to inherent properties of the bacterial pathogens that render them resistant. Some examples include *Mycoplasma* species that are inherently resistant to penicillin due to the lack of a cell wall.

Acquired resistance occurs from horizontal transfer of resistance genes from other organisms. Gene sequences that bring about this horizontal transfer include plasmids, transposons and gene cassettes. Multiple mechanisms may act in concert, resulting in drug resistance. For example, *E. coli* can become resistant to multiple agents by acquiring chromosomally-mediated, or plasmid-encoded beta-lactamases, and up regulation of efflux pumps. Basic mechanisms that lead to bacterial resistance to antimicrobial agents include the following: (1) alteration of the antimicrobial binding site; (2) enzymatic inactivation or alteration, active efflux, and alterations in membrane permeability to prevent antimicrobial entry.

Detection of Antimicrobial Resistance

Understanding whether an antibiotic has adequate antibacterial activity against the suspected pathogen is critical for ensuring successful therapy. In some situations, susceptibility testing may be unnecessary, as in the case of infection with *Streptococcus pyogenes*, which is well-known to be exquisitely susceptible to penicillin. The MIC value provides an operational definition of the bacterial strain's intrinsic antibiotic susceptibility, incorporating all the additive effects of multiple mechanisms of resistance. The MIC values at which an organism is considered *susceptible* (S), *intermediate* (I) or *resistant* (R) are called breakpoints. A report of S indicates that treatment with

standard approved doses of the antibiotic should be expected to lead to clinical success as long as the tissue concentration of the antibiotic is similar to the serum concentration. A report of R suggests that microbiological cure is not achievable, as the antibiotic does not inhibit the bacterial pathogen at the standard dosing rate. MICs can have limitations and can vary according to site of infection. For example, an isolate of *Staphylococcus aureus* may be reported as susceptible to cefazolin in vitro based on the MIC; however, if this particular isolate was obtained from the cerebrospinal fluid (CSF), cefazolin would be a poor therapeutic choice because it does not achieve therapeutic concentrations in the CSF.

Different types of susceptibility tests include the disc diffusion test (Kirby-Bauer), an antibiotic strip gradient-diffusion test (E-test), agar dilution with a mechanized inoculator, broth macrodilution or microdilution test. Automated commercial test systems are also available. In addition to these traditional methods, molecular detection of bacterial resistance is gaining popularity. These susceptibility tests have been standardized and provided with standard thresholds and interpretations by the Clinical and Laboratory Standards Institute (CLSI), a nonprofit global organization that develops susceptibility standards through extensive laboratory testing and clinical correlation. Certain modified tests may be used in order to detect specific types of resistance in pathogens that have special clinical significance. Examples include disc diffusion testing for ESBL detection (**Fig. 2**) and PCR-based testing for *mecA* gene in resistant *Staphylococcus aureus*.

Prevention of Emergence of Antimicrobial Resistance

This can be achieved through judicious antibiotic prescribing (**Box 2**), whose important components include restraint of antibiotic treatment for community-acquired, mostly viral, upper respiratory tract infections; use of narrow-spectrum antibiotics when possible; and use of antibiotics for the shortest duration that is effective for bringing about improved clinical outcomes. The use of rapid diagnostic tests and biomarkers can also help toward better diagnosis of viral infections, and toward more careful use of empiric antibiotics in these settings.

Figure 2 Disc diffusion testing for extended spectrum beta-lactamase (ESBL) production in *Klebsiella pneumoniae* lawn culture in a petri dish. The inhibition zone around the ceftazidime/clavulanic acid-containing disc (CAZ/CVA) is larger than that around the disc containing the corresponding cephalosporin alone (CAZ). An increase of 5 mm or more around the beta-lactam/beta-lactamase disc is indicative of ESBL production

Abbreviation: CTX, ceftioxiime.

BOX 2 Tips for prescribing antibiotics*For outpatients*

- Limit prescribing over the telephone to exceptional cases where there is a strong evidence of clinical benefit
- Consider a nonantibiotic strategy for common upper respiratory infections, such as acute cough, common cold and acute sinusitis
- When prescribing an antibiotic, always pay attention to the dose and the duration
- Avoid overuse of broad spectrum antibiotics (e.g., amoxicillin-clavulanic acid, quinolones and cephalosporins) as this can increase risk of resistant infections, and can also limit the future usefulness of these agents. Consider use of narrow spectrum agents (e.g., penicillin, amoxicillin, trimethoprim) for specific indications when clinically appropriate
- Avoid widespread use of topical antibiotics (especially those agents also available as systemic preparations, such as colistin and fusidic acid)

For inpatients

- Define the infection in three possible ways: anatomically, microbiologically and pathophysiologically
- Obtain microbiological cultures before starting antibiotics
- Use imaging, rapid diagnostics and special procedures early in the course of infection
- Do not rely solely on *response to therapy* to guide therapeutic decisions; follow recommended guidelines
- If empiric therapy is started, reassess at 48–72 hours, and proceed to targeted therapy as soon as possible by de-escalating antibiotics
- Check drug doses and interactions with co-administered drugs
- Document antibiotic start date and planned duration of treatment clearly.

ANTIMICROBIAL STEWARDSHIP (ALSO SEE CHAPTER 27.3)

Overuse of antimicrobials can ultimately be a threat to their effectiveness. The emergence and spread of antimicrobial resistance complicates therapy, raises costs and increases the likelihood of treatment failure. Antimicrobial stewardship programs are aimed to optimize selection of antimicrobials, restrict their inappropriate use, optimize dose, route and duration of treatment for best outcomes, limit costs, adverse events and emergence of resistance. Typically, a multidisciplinary team constitutes the antimicrobial stewardship program, consisting of an infectious disease physician, clinical microbiologist, clinical pharmacologist, infection control nurse and hospital administrator. Critical components of antimicrobial stewardship include the following: prospective

audit and feedback of antimicrobial prescriptions to clinicians, formulary restriction, education, use of clinical guidelines, de-escalation of therapy, and expeditious conversion of antimicrobial from intravenous to oral route when appropriate.

IN A NUTSHELL

1. Antibiotics are remarkable tools that have played a spectacular role in maintaining health and prolonging life.
2. Prescribing an antibiotic in the most appropriate manner possible is a serious responsibility that health workers should collectively shoulder.
3. This task involves having an acute knowledge of the costs, risks and benefits of antibiotic use, making an informed and accurate diagnosis, determining the need for and timing of antibiotic therapy, understanding dosing effects, tailoring treatment to host characteristics, using the narrowest spectrum and shortest duration of therapy, and switching to oral agents as soon as possible.
4. Teamwork is essential in these activities, and these principles of antibiotic use may be pursued diligently to provide the best possible care for patients.

Chapter 29.3

Diphtheria

Prerna Batra, Piyush Gupta

Diphtheria is an acute infectious disease, caused by a toxin producing bacillus *Corynebacterium diphtheriae*. The classic presentation is respiratory disease characterized by formation of pseudomembrane over tonsils. Uncommonly, the disease can also affect skin, eyes, ears or genitals. The patient usually presents with fever and signs localizing to the affected organ system. Asymptomatic human carriers are the reservoirs for the bacilli. Despite good coverage with vaccination in developed countries, diphtheria continues to occur with breach of immunization. The disease is endemic in developing countries from Africa, Latin America, Asia and Middle East.

EPIDEMIOLOGY

Diphtheria is prevalent worldwide. Number of cases, morbidity and mortality declined following introduction of vaccine in the late 1940s. In the United States, epidemics occurred during 1990s, with case fatality rates varying from 3 to 23%. After 2003, no case of respiratory diphtheria has been reported from the US, a significant change in epidemiology. Outbreaks keep on occurring in developing countries. A major outbreak was reported from countries of Soviet Russia in 1990s. Nigeria had a major outbreak of diphtheria in 2011, where none of the 98 patients affected were vaccinated. A shift of the disease towards adult patients has been noticed due to waning immunity with increasing age. In India, diphtheria is an endemic disease, though showing a decrease in number of cases because of widespread coverage of vaccination. Peak incidence is the cooler months of autumn, winter and spring season.

ETIOLOGY

Corynebacterium diphtheriae is an aerobic gram-positive pleomorphic bacillus. When grown on a special medium (Löeffler's medium), it exhibits a characteristic club shape. The organism can also be readily grown in tellurite cysteine medium (tellurite).

Corynebacterium diphtheriae produces a powerful exotoxin, responsible for its virulence. Diphtheria toxin is a 58 kDa polypeptide, containing fragment A (21 kDa) and fragment B (37 kDa). Fragment A is the biologically active form that catalyzes transfer of adenosine diphosphate ribose (ADPR) from nicotinamide adenine dinucleotide (NAD) to elongation factor 2 (EF-2). Fragment B contains the receptor-binding domain that is responsible for passage of toxin through the target cell. *C. diphtheriae* strain can be either toxigenic or nontoxigenic, depending on its ability to be lysogenized by *tox*⁺ gene carrying corynephage. *Corynebacterium ulcerans* and *Corynebacterium pseudotuberculosis* strains are capable of producing diphtheria toxin and clubbed under *C. diphtheriae* group. Cardiac, renal and neurological sequelae are observed following infection with toxigenic strains only, whereas nontoxigenic strains lead only to sore throat and rarely invasive infections.

Four biotypes of the organism are reported: mitis, intermedius, gravis and belfanti. Gravis biotype is considered to be most toxigenic. Olu, *et al.* identified eight genotypes of the organism by multilocus DNA sequencing (MLST) in Russia between 2002 and 2012. Most of the toxic strains belonged to gravis biotype and ST 8 genotype.

PATHOGENESIS

Corynebacterium diphtheriae gains entry into human body via oral or nasal route either through direct contact or through droplet infection. The organism is carried in the upper respiratory tract or skin of asymptomatic carrier. At times, ocular or genital tract may also harbor the microbe. Incubation period is 2–7 days. After this incubation period, the organism starts producing toxin. The primary local lesion consists of necrotic injury to epithelial cells in the upper respiratory tract. As a result of this injury, blood plasma leaks into the area and a fibrin network forms, which is interlaced with rapidly-growing *C. diphtheriae* cells. This membranous network covers the site of the local lesion and is referred to as the *pseudomembrane*. This is a whitish, tough membrane that is adherent to underlying tissues and is difficult to remove. Over a period of days, it becomes gray and later on develops green or black spots, because of necrotic areas.

The diphtheria bacilli do not tend to invade tissues below or away from the surface epithelial cells at the site of the local lesion. At this site, the toxin produced is absorbed and disseminated through lymph channels and blood to the susceptible tissues of the body. Degenerative changes in these tissues, which include heart, muscle, peripheral nerves, adrenals, kidneys, liver and spleen result in the systemic pathology of the disease. Cardiac manifestations appear after a latent period of 10–14 days and CNS manifestations after 3–6 weeks. Histologic studies of the cardiac tissues have shown necrosis, hyaline degeneration, mononuclear infiltration and fatty accumulation in the myocardium. Affected nervous tissue is characterized by degenerative changes in the myelin sheath and axons. These changes lead to peripheral neuritis in children with diphtheria. Necrosis and hyaline changes may be seen in liver. Acute tubular necrosis may occur in kidneys of the affected individual.

CLINICAL FEATURES

Centre for Disease Control (CDC), USA classifies diphtheria into various clinical manifestations depending upon the site of involvement. A review of 676 cases of diphtheria from Kyrgyz republic during an outbreak from 1994 to 1998 showed that 28% of patients had tonsillar presentation and 30% had severe forms of diphtheria.

Anterior Nasal Diphtheria

It is a relatively milder form of disease, more commonly seen among infants and younger children. Child presents with mild fever, sore throat and mucopurulent nasal discharge. Pseudomembrane develops over the nasal septum, which sloughs off leading to blood-tinged discharge.

Pharyngeal and Tonsillar Diphtheria

It is the commonest form of diphtheria. The illness is characterized by insidious onset with sore throat, fever, malaise and loss of appetite. After 1 or 2 days, exudate appears adjacent to tonsils that coalesce to form a pseudomembrane covering pharynx, tonsils and uvula. Associated cervical lymphadenopathy also develops. The child may develop marked edema of anterior neck, giving characteristic 'bull neck' appearance. Features of upper respiratory tract obstruction may develop in the form of dysphagia, drooling of saliva, and difficulty in breathing. A more severe and toxic form of presentation with rapid deterioration leading to respiratory and circulatory collapse may also occur.

Laryngotracheal Diphtheria

Laryngotracheal diphtheria is a severe form of diphtheria where patient is more prone to respiratory compromise. This occurs as a result of downward spread of membrane from pharynx. These patients present with noisy breathing, stridor, hoarseness of voice and dry cough. The illness becomes fatal if respiratory obstruction is not rapidly relieved.

Cutaneous, Ocular and Genital Diphtheria

Cutaneous diphtheria It is more common in overcrowded conditions and in tropical states. Though the lesion does not have a characteristic appearance, it is usually an ulcerated painful lesion, with ill-defined margins, surrounding erythema and membrane. Healing takes 2–3 months but rarely may persist for a year.

Ocular Diphtheria Ocular lesions are characteristically conjunctival lesions, mainly over the palpebral conjunctiva.

Genital Diphtheria Vulvovaginal form of disease is also seen. Other rare presentations of disease include meningitis, osteomyelitis, arthritis and hepatitis.

COMPLICATIONS

The toxin elaborated by diphtheria bacillus can cause damage to cardiac, neural and renal tissue. The extent of secondary damage depends upon the severity and extent of the primary disease and amount of antitoxin circulating in the body.

Myocarditis Myocarditis is seen in 10% of affected patients. It usually develops during 1st week of illness and leads to dysrhythmias and cardiac failure. The child has tachycardia and muffled heart sounds.

Neuritis Neuritis affecting motor nerves is seen in 75% of severe cases. Neural involvement starts in the 2nd week of illness with palatal involvement and then descends to involve pharyngeal, laryngeal and diaphragmatic muscles. This disease progresses till 6th week of illness. During the course of disease, patient may succumb due to respiratory complications. Recovery starts after a few weeks. The manifestations start with a nasal twang in voice, nasal regurgitation, dysphagia and drooling of saliva. Loss of accommodation and difficulty in vision develops with ocular muscle involvement. Motor weakness is symmetrical and simulates Guillain-Barre syndrome. Neural complications are self-limiting.

Renal failure Child may rarely develop renal failure as a complication of diphtheria which is often fatal. A report from Chandigarh, India showed renal failure in 17 out of 48 patients, out of which 15 died, though they were shown to have coexistent myocarditis and cardiogenic shock.

Other reported complications of diphtheria include endocarditis, thrombocytopenia leading to skin bleeds, otitis media, and subcapsular hemorrhage in spleen.

DIFFERENTIAL DIAGNOSIS

Diagnosis of diphtheria is often clinical. In emergency setting for the purpose of prompt initiation of specific management, it needs to be differentiated from some other common illnesses seen in children. Differential diagnoses are usually pertaining to the site of involvement.

Nasal diphtheria in its milder form resembles common cold. Other conditions that may mimic the condition are snuffles, foreign body, sinusitis and adenitis. Streptococcal sore throat closely resembles pharyngeal diphtheria. Acute onset, high grade fever and absence of pseudomembrane help differentiate the condition. The clinical picture may at times be confused with

infectious mononucleosis and Vincent's angina. Other differential diagnoses include viral pharyngeal infections, like herpetic tonsillitis, adenovirus and cytomegalovirus infection. Laryngeal involvement in diphtheria needs differentiation from croup and croup-like illnesses, epiglottitis and foreign body. Genital lesions in an adolescent may be confused with sexually transmitted diseases. Neurological complications of diphtheria mimic acute flaccid paralysis because of Guillain-Barré syndrome.

APPROACH TO DIAGNOSIS

A careful history including the onset and progression of symptoms, and examination with visualization of pseudomembrane helps in establishing the correct diagnosis. Supportive laboratory investigations further help. The diagnosis is finally confirmed by isolation of organism from the lesion.

Culture of the Organism

In suspected cases, an attempt should be made to obtain a specimen for staining and culture of the organism from the site of infection. The swab can be obtained from nasopharynx, oropharynx, tonsils, cutaneous or genital lesions. Multiple, inflamed areas should be swabbed. If pseudomembrane is seen, the sample should also be taken from the area beneath the membrane. It is important to inform the laboratory regarding the suspicion of diphtheria in advance, so that appropriate culture media are used. As the bacteria are relatively resistant to drying, it may be transported to laboratory in Amies medium. Swab is plated on Löeffler's medium or tellurite. After 8–18 hours, staining of the growth with methylene blue reveals club-shaped diphtheroid cells containing metachromatic granules. *Elek test* should be performed on the organism isolated to test for toxigenicity. The test is based on gel diffusion and immunoprecipitation technique. The results are available in 48 hours.

Rapid Diagnostic Tests

Enzymatic assay to detect diphtheria toxin by using equine polyclonal antibody is now available. The test is rapid and gives diagnosis in 3 hours. Polymerase chain reaction (PCR) for detection of either 'A' or 'B' portion of *tox* gene is also available. The concern with these tests is the cost associated with these and poor availability.

Other Hematological and Biochemical Tests

These tests do not have a role in establishing the diagnosis. Presence of leukocytosis (TLC > 25,000/μL) has prognostic value. Thrombocytopenia may be seen in patients with complications of diphtheria and disseminated intravascular coagulation (DIC). Hemoglobin may be on lower side of normal range. Hepatic complications may lead to hypoglycemia, glycosuria and raised liver enzymes. Blood urea nitrogen (BUN) and creatinine are elevated in presence of acute tubular necrosis. Cerebrospinal fluid (CSF) examination reveals raised protein levels, but cell count and sugar levels are normal. Cardiac complications may reveal ECG changes in the form of tachycardia, low voltage and arrhythmias.

MANAGEMENT

Specific treatment with *antitoxin* and *antibiotics* should be initiated immediately while bacteriological investigations are still pending. Antitoxin therapy is the mainstay of therapy. Antibiotic therapy is required to eradicate the organism and prevent spread. Mechanical airway obstruction and myocarditis are the main causes of death in toxigenic disease and careful supportive management is required.

Specific Therapy

Diphtheria Antitoxin

Diphtheria antitoxin is hyperimmune serum produced in horses. Antitoxin will only neutralize circulating toxin that is not yet bound to tissue, thus prompt administration is critical. Delayed administration increases the risk of late effects, such as myocarditis and neuritis. Before antitoxin is administered, the patient should be tested for sensitivity to horse serum and, if necessary, desensitized. Sensitivity testing is done by administering 0.02 mL of 1:1000 dilution of antitoxin intradermally. Alternatively, 1:10 dilution of antitoxin can be instilled into conjunctival sac or a drop can be administered intradermally in 1:100 dilution. If there is a sensitivity reaction, desensitization is required. Desensitization is done by giving slowly increasing dosages of antitoxin every 15 minutes intravenously. To start with, 1:1000 dilution is used, which is gradually increased to undiluted antitoxin. If acute anaphylaxis develops, intravenous epinephrine (0.2–0.5 mL of 1:1000 solution) be administered immediately by intravenous injection.

The dose of antitoxin to be administered depends upon the site and extent of the diphtheritic membrane, the degree of toxicity and the duration of illness. **Table 1** indicates the suggested dose range for various clinical situations. Role of antitoxin in cutaneous form of disease is controversial, although some centers advocate 20,000–40,000 units of antitoxin because toxic sequels have been reported.

Table 1 Dosage of antitoxin recommended for diphtheria

Type of diphtheria	Dosage (units)	Route
Nasal	10,000–20,000	IM/IV
Tonsillar	15,000–25,000	IM/IV
Pharyngeal or laryngeal	20,000–40,000	IM/IV
Combined types or delayed diagnosis	40,000–60,000	IV
Severe diphtheria with respiratory obstruction or bull-neck	40,000–1,00,000	IV or part IV and part IM

Abbreviations: IV, intravenous; IM, intramuscular

Antibiotics

Antibiotic treatment is necessary to eliminate the organism and prevent spread; it is not a substitute for antitoxin treatment. The antibiotics of choice are penicillin or erythromycin. Additional advantage of using penicillin is that it is also effective against Group A β hemolytic *Streptococcus*, which complicates almost one-third of these patients.

Crystalline penicillin (1,00,000–1,50,000 units/kg/day in four divided doses) intravenously or procaine penicillin G (25,000–50,000 units/kg/day in two divided doses) intramuscularly are the initial therapeutic options. One can shift to oral erythromycin (40–50 mg/kg/day in 4 divided doses) or oral penicillin V (125–250 mg twice daily) when the patients is able to swallow. Antibiotic treatment should be continued for 14 days. The organism shows in vitro susceptibility to other drugs, like clarithromycin, azithromycin, amoxicillin, rifampin and clindamycin also, but their role in treatment of the disease is not yet proven.

The treatment should be followed by repeating culture 2 weeks after completion of antibiotics. If culture still remains positive, additional course of erythromycin should be given for 10 days. Two to three consecutively negative cultures taken 24 hours apart suggest the cure.

Treatment of Carriers

Carriers should be treated with erythromycin 40 mg/kg/day for 7–10 days or a single intramuscular dose of benzathine penicillin (0.6 mega units for < 30 kg weight and 1.2 mega units for > 30 kg). Cultures should be obtained after two weeks. If positive, give an additional course of erythromycin for 10 days.

Unimmunized carriers should receive a full schedule of active immunization. Previously immunized carriers should receive a booster dose if the previous dose was received more than a year ago.

Supportive Therapy

Diphtheritic infection has a high likelihood of letting into life-threatening complications as discussed earlier. Management of ABC (airway, breathing and circulation) should be prime importance. Frequent suctioning of secretions to prevent aspiration should be done. Patient should be monitored for oxygen saturation by pulse oximetry, and oxygen supplementation should be provided, if there is hypoxia. Ventilation should be supported if required. Intravenous fluids should be given and monitoring for earliest evidence of shock be done. In stable patients also, bedrest is required for at least 2–3 weeks. Child should be monitored carefully for development of complications for 4–6 weeks. Serial ECG monitoring may be done.

PROGNOSTIC FACTORS

Diphtheria carries a high case fatality rate. Immunization status of the host remains the most important prognostic factor. Early initiation of antitoxin therapy markedly improves the outcome. The disease is likely to be more fatal among infants and older age group of patients. Toxigenicity of the agent, i.e., *C. diphtheriae* is found to relate with the severity of complications. Nontoxigenic strains may cause the disease, but complications like myocarditis, neuritis and renal failure do not occur as these are toxin-mediated. Amongst toxigenic strains, *gravis* is the most severe of all. Presence of leukocytosis, thrombocytopenia and other systemic complications mark a poorer prognosis.

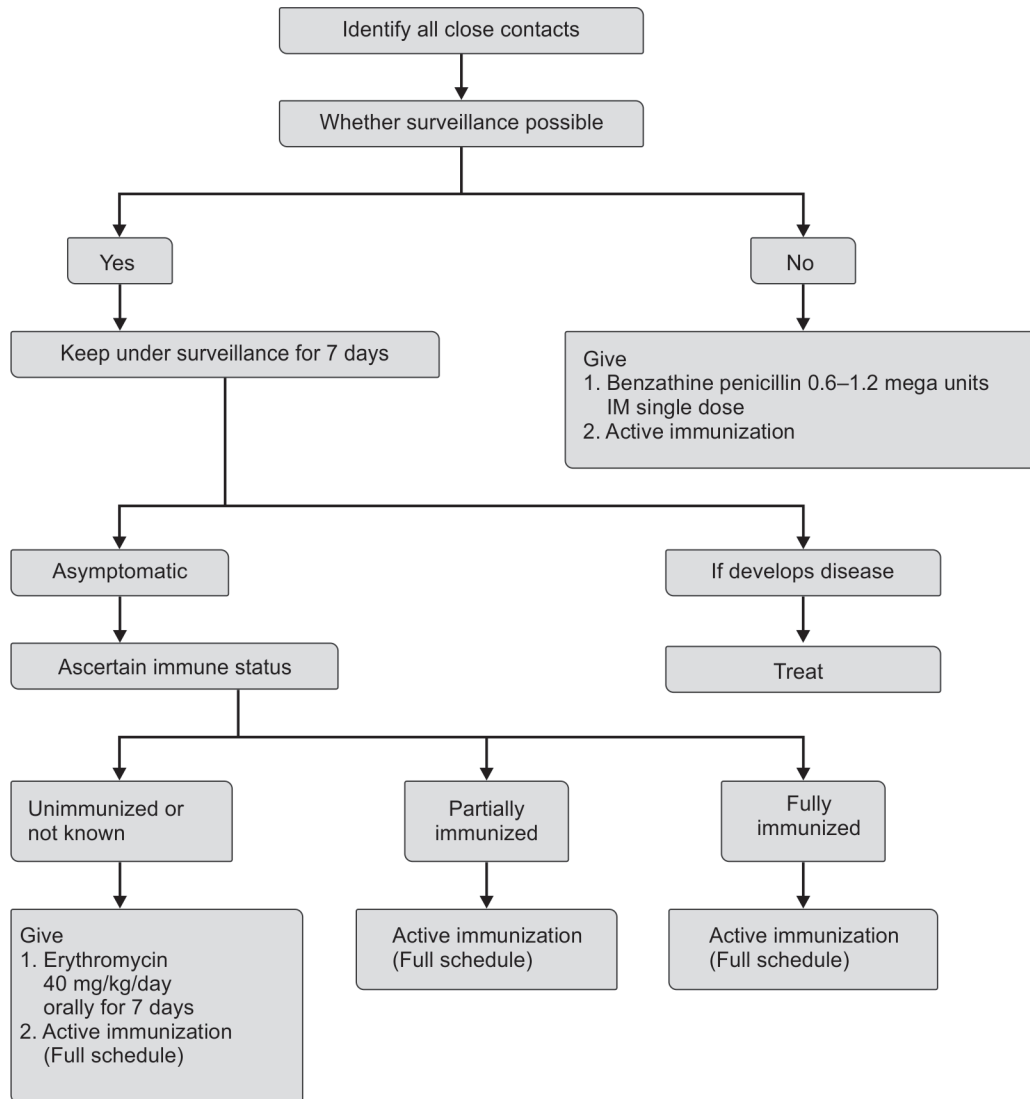

PREVENTION

Isolation of the patient Communicability in untreated persons lasts for two weeks, and in treated adequately, for less than four days. The patient should be isolated until this period is over or two cultures from nose and throat are negative.

Care of the contacts Management of close contacts is given in the **Flow chart 1**. There is no role of prophylactic diphtheria antitoxin in unimmunized close contacts.

Active immunization Currently available diphtheria vaccine is a toxoid, available as DPT vaccine. **Primary immunization** consists of three doses at an interval of 4–6 weeks, starting from 6 weeks after birth. First booster is given at 18 months and a second booster at 5 years. Subsequent boosters are not necessary in India where *C. diphtheriae* infection is common. If the primary immunization is to be carried out in adult or older child, the adult type of toxoid (Td) containing less quantities of antigen should be employed.

In the light of recent diphtheria outbreaks affecting older children and younger adults in developing countries and the resurgence of the disease in industrialized countries, it has become clear that periodic administration of booster doses of diphtheria toxoid is needed to ensure long-lasting protection of all individuals against diphtheria. Thus, TT should be replaced with Td in a phased manner.

Flow chart 1 Care of contacts of a patient with diphtheria**IN A NUTSHELL**

1. Diphtheria is a potentially fatal disease caused by exotoxin producing bacteria *C. diphtheriae*.
2. Presence of pseudomembrane on the affected site is pathognomonic of the disease.
3. Diphtheria may have various clinical presentations, namely nasal, pharyngeal and tonsillar, laryngeal, cutaneous, ophthalmic or genital.
4. Pharyngeal diphtheria is commonest and these patients have a high likelihood of developing respiratory failure.
5. Myocarditis, neuritis and renal failure are potential complications, for which patients need close monitoring.
6. Diagnosis is established by isolation of organism in special culture media.
7. Patients need to be started with antitoxin on the basis of clinical diagnosis as soon as possible.
8. Main role of antibiotics, i.e., crystalline penicillin and erythromycin is to prevent further transmission of the disease.
9. Carriers and close contacts should be managed as per the standard protocols.
10. Primary immunization with diphtheria toxin is a must for prevention.

Chapter 29.4

Pertussis

Piyush Gupta, Prerna Batra

Pertussis is a highly communicable disease of respiratory tract caused by *Bordetella pertussis*, and at times by *B. parapertussis*. The disease is characterized by paroxysms of cough and a peculiar inspiratory sound *whoop*. Pertussis is known to affect all the age groups, but more often diagnosed in young children. Infants less than 3 months of age carry poor prognosis. The disease is endemic worldwide.

EPIDEMIOLOGY

Pertussis is highly infectious, with secondary attack rate up to 90%. Outbreaks of pertussis are reported since 16th century. The number of outbreaks declined after 1940, after the introduction of whole cell pertussis vaccine. However, disease resurgence was noticed in 1980s all over the globe. This pattern has been seen in all parts of the world; Australia, Netherlands, United Kingdom, United States, Italy and Brazil just to name a few. South Asian countries have shown a similar trend, with major outbreaks reported from Afghanistan, Thailand, Israel and Taipei. In 2007, an outbreak was reported from Arunachal Pradesh in India, with attack rate of 30%. Possible reasons for this resurgence are increased vaccine failures from genetic changes in *B. pertussis*, waning immunity, better diagnostic abilities due to better laboratory facilities, and greater awareness of the disease. Another important reason being considered is shift from whole cell vaccine to a less potent acellular vaccine. The contributions of these reasons, however, vary in different regions of the world. Another trend reported in recent years is shift to adolescents and adults.

Man is the only reservoir for *B. pertussis*. Transmission of infection occurs mainly via direct contact or through droplets by coughing. Pertussis cases are seen throughout the year; still a rise in number is observed during summer and fall in most of the regions. The transmission increases with overcrowding, poor hygienic conditions and close contact. Asymptomatic carriers exist and carry infection for a short duration. A female preponderance is seen for reasons unknown.

ETIOLOGY

Bordetella pertussis is the causative organism in more than 95% of cases, with remaining few caused by *B. parapertussis*, *B. bronchiseptica*, and *B. holmesii*. *B. pertussis* is an aerobic, gram-negative, pleomorphic coccobacillus. It contains a variety of biologically active and antigenic substances. These include fimbriae (FIM), filamentous hemagglutinin antigen (FHA), pertactin (PRN), other surface-associated proteins like Vag8, BrkA, Sph B1, tracheal colonization factor (tcfA), pertussis toxin (PT), adenylate cyclase toxin (ACT), dermonecrotic toxin (DNT), tracheal cytotoxin, and lipopolysaccharide (LPS) endotoxin. Fimbriae are highly immunogenic and antibodies to them, along with other antigens, cause agglutination of the organism. FHA is also an immunogenic component of cell wall of *Bordetella* species and is the component of most acellular vaccines. Pertussis toxin produced by *Bordetella* adversely affects host immune functions and is responsible for severity of morbidity associated with the illness. It also contributes to lymphocytosis. ACT, DNT and tcfA cause local damage to respiratory tract.

Virulence of *B. pertussis* is regulated by a single gene *bvgAS*. In the presence of favorable conditions, this gene is activated (*bvg+*) and leads to formation of various antigens and toxins except tcfA. The phenomenon has been proven in animal models.

PATHOGENESIS

Infection with *B. pertussis* is followed by attachment of bacteria to respiratory tract epithelium, evasion of host defense, local damage, and systemic disease. Attachment is mediated by various adhesins present on the surface of *Bordetella* as described above. Ciliary damage to the respiratory epithelial surface initiates inflammation. There is interference of pulmonary secretion clearance. Histopathology of lung tissue after autopsy from 15 infants with fatal pulmonary pertussis infection showed necrotizing bronchiolitis, intra-alveolar hemorrhage and fibrinous edema. PT causes lymphocytosis and deterioration in cell-mediated immunity. Incubation period is 7–10 days, and may extend up to 3 weeks.

CLINICAL FEATURES

Severity of clinical features depends on various factors, which include age, immunization status, passively acquired immunity, degree of exposure and genotype of the organism. Classically, the disease is characterized by three distinctly identifiable stages.

1. Catarrhal Stage

Disease manifestations start with a mild respiratory illness, resembling common cold. Patient has mild fever, running nose, sneezing and mild cough. Catarrhal stage lasts for 1–2 weeks. Symptoms may be minimal among young infants during this stage.

2. Paroxysmal Stage

This is the stage of classic presentation of pertussis when most of the cases are identified. The child presents with increased severity of cough that occurs in bouts. At the end of the bout, patient forcefully inspires through a narrow glottis producing the characteristic *whoop*. Paroxysm is associated with cyanosis, suffusion of the face, bulging eyes, protrusion of tongue, excessive salivation, lacrimation and post-tussive vomiting. Patient may have several spasms during a span of 24 hours. The patient gets exhausted and has difficulty in feeding during spasms, though appears comfortable in between these bouts of cough. The stage may last for 1–6 weeks.

3. Convalescent Stage

During this stage, spasms become less frequent and severity of coughing decreases. Clinically, it may be difficult to clearly differentiate it from paroxysmal stage. This stage may last up to 3 months. The disease is, therefore, a prolonged course, with cough being the prominent feature, commonly called *cough of 100 days*.

Previously vaccinated children may have a mild, nonclassic illness. Yaari, *et al.* studied the profile of serologically confirmed pertussis patients from Israel. Mean duration of cough was 23 days, with majority not having the whoop.

In infants, pertussis has an atypical presentation. Manifestations depend on the age of presentation, immunization status and levels of transplacentally acquired antibodies. The baby may develop choking, gasping, apnea and bradycardia as a result of severe spasm of cough. Whoop may be absent in these patients. Young infants also develop difficulty in feeding and this prolonged illness along with feeding difficulty may lead to failure to thrive.

Complications

Complication rate with pertussis is very high among infants less than 6 months of age. These complications mostly are either because of the violent cough or may be pulmonary or neurological. Severe spasmodic cough in the stage of paroxysms may lead to rupture of alveoli and development of subcutaneous emphysema. The patient may even develop subconjunctival bleed, subcapsular bleed, subdural bleed, umbilical hernia and inguinal hernia. At

times, the intensity of cough may be strong enough to even lead to rib fracture.

Pulmonary complications include pneumonia, otitis media and pulmonary hypertension, whereas neurological complications include seizures, encephalopathy and polyneuropathy. The complications occur either due to *Bordetella* per se or as a result of secondary bacterial infection, or may even be because of severe hypoxia. Organisms that have been isolated from patients with secondary bacterial infection include *S. pneumonia* and *Mycobacterium tuberculosis*.

Recurrent vomiting may cause metabolic alkalosis, dehydration and failure to thrive.

DIFFERENTIAL DIAGNOSIS

Clinical diagnosis of pertussis is suspected on the basis of severe spasmodic cough, with post-tussive vomiting and apparently well child in between these spasms. But, there are certain other infectious agents that cause similar prolonged protracted cough and are often confused with whooping cough. These are mostly viral infections, like adenovirus, respiratory syncytial virus (RSV) and atypical organisms including *Mycoplasma* or *Chlamydia*. Other chronic pulmonary conditions, like hyper-reactive airway disease, cystic fibrosis and bronchiectasis, fungal or even tubercular infection may mimic pertussis. Another differential diagnosis which one must consider while dealing with a small child with prolonged cough is gastroesophageal reflux disease (GERD).

APPROACH TO DIAGNOSIS

Diagnosis of whooping cough is usually clinical and certain hematological investigation may help to support the diagnosis. Case-definition for pertussis is depicted in **Box 1**.

BOX 1 Case definition for pertussis

Suspected case

History of severe cough lasting for 2 weeks or more (84–92% sensitivity and 3–90% specificity, during outbreaks)

Probable case

Any of the following in a suspected case:

- Prolonged coughing followed by a period of apnea and cyanosis, or in older children paroxysms of coughing followed by vomiting, or a typical breath intake and 'whoop', or subconjunctival hemorrhages
- Exposure of a suspect case in the previous 3 weeks
- Epidemic of whooping cough in the area
- Lymphocytosis of $15000/m^3$ or more

Confirmed case

- Laboratory evidence of *B. pertussis* from the culture or immunofluorescence of nasopharyngeal secretions
- A case that is directly linked epidemiologically to a case confirmed by PCR or culture.

Specific laboratory diagnosis of pertussis is established by isolation of organism on appropriate medium or by documenting the presence of organism by polymerase chain reaction (PCR) or direct fluorescence antibody (DFA) testing. Culture is the gold standard for diagnosis of pertussis. Organism can be isolated from nasopharyngeal secretions obtained by aspiration or by swabbing (calcium alginate or dacron). Aspirates give best yield of organism required for the growth. Culture should be directly inoculated into *Regan-Lowe* or *Bordet-Gengou agar* media. Direct fluorescence antibody test, though rapid, has a poor sensitivity and specificity, and, hence, is no longer recommended. Leukocytosis with absolute lymphocytosis in peripheral smear also supports the diagnosis of pertussis. PCR has a better specificity than sensitivity,

especially in previously immunized patients. The sample taken is nasopharyngeal aspirate or swab, but swab should not be calcium alginate swab.

MANAGEMENT

Treatment of pertussis is primarily supportive. Adjunct therapy should center on five principles of care (**Box 2**). Affected child may look completely asymptomatic between the episodes of devastating cough. Mild sedation should be administered to allay anxiety. Humidification of the air diminishes the viscosity of mucus and the affected child can bring it out more easily. Gentle suctioning may be done. Patients should be monitored for development of complications. Severe cases may need intravenous hydration, oxygen supplementation and nutritional support. Salbutamol and corticosteroids have no role in reducing the severity of paroxysms.

BOX 2 Principles of treatment for pertussis

- Avoid provoking paroxysms of coughing
- Comforting during paroxysms
- Clearing away mucus and vomit during paroxysms to prevent inhalation
- Early recognition and treatment of complications
- Maintaining good hydration and reasonable nutrition.

Antibiotic Therapy

Antibiotics are effective only in the catarrhal stage of the disease. Once in the paroxysmal phase, drug therapy makes little impact on the course of the illness. *B. pertussis* and *parapertussis* have shown in vitro sensitivity towards many antibiotics.

Erythromycin (40 mg/kg/d orally in 4 divided doses) is considered as drug of choice against *Bordetella pertussis*. It renders the sufferer noninfectious after 5 days of treatment; however, the drug is best continued for 2 weeks as a few individuals remain culture positive even after 1 week of antibiotics. Resistance has been reported. Newer macrolides (e.g., azithromycin, clarithromycin) are potential alternatives for patients who cannot tolerate erythromycin. Azithromycin is typically administered in doses of 10–12 mg/kg/d orally once a day for 5 days. Dose of clarithromycin is 15–20 mg/kg/d orally in 2 divided doses, not to exceed 1 g/d for 5–7 days. Since use of erythromycin has been shown to be associated with idiopathic hypertrophic pyloric stenosis (IHPS) in infants younger than 1 month of age, azithromycin is the drug of choice for neonatal pertussis.

Trimethoprim-sulfamethoxazole (trimethoprim 8 mg/kg/d and sulfamethoxazole 40 mg/kg/d) in 2 divided doses is another antibiotic option, especially for infants more than 2 months of age who either cannot tolerate macrolides or have a macrolide resistant strain.

Care of Contacts

The Committee on Infectious Diseases of the American Academy of Pediatrics currently recommends promptly treating all household and other close contacts (e.g., children and staff at daycare centers) with erythromycin to limit secondary transmission. This is regardless of the age or immunization status of contacts. A 14-day course of oral erythromycin (40–50 mg/kg/d in 4 divided doses) is recommended for close contacts. Some experts prefer the estolate preparation in young infants because of more effective absorption, which may lead to decreased dosing and less frequent dosing intervals.

Patients of whooping cough remain infectious for a long time and, hence, they should remain isolated until 3 weeks after the onset of paroxysms of cough.

PROGNOSIS

Prognosis depends upon the age of the patient. Infants have a poorer prognosis with a high risk of neurological complications. Immunization status of the child is another important prognostic factor. The disease is much more severe in unimmunized and partially immunized patients.

PREVENTION

Natural disease does not provide life-long immunity. Similarly, pertussis vaccination protects the individual for a maximum period of 10–20 years. However, universal immunization of children with pertussis vaccine is essential for control of pertussis. Since protective antibodies against this disease do not cross the placenta, early immunization is desired. It has been seen that four primary doses of whole cell pertussis vaccine provide 70–90% protection against serious pertussis disease. National Immunization Schedule of India advocates pertussis vaccination as DPT (diphtheria, pertussis and tetanus, commonly known as triple vaccine) at 6, 10 and 14 weeks of age. This is to be followed by 2 boosters at 18–24 months and at 5 years of age. Whole cell vaccine (DPwT) is known to cause local reactions and mild systemic reactions. These complications are mostly due to pertussis component. There is no scientific basis to the general belief that pertussis does not affect children more than 5–6 years of age. Adult pertussis is known to occur and immunity wanes by next 6–12 years, hence, booster dose is recommended.

Acellular Pertussis Vaccine

Studies have clearly indicated that DPT with a whole cell pertussis (wP) component is responsible for frequent reactions. These reactions are both unpleasant and at times dangerous. This led to the development of acellular pertussis vaccine in the year 1981 in Japan. The acellular vaccine predominantly contains PT as the essential component, and different amounts of filamentous hemagglutinin (FHA), pertactin (PRN) and fimbrial hemagglutinins 1, 2 and 3 (FIM 1, 2, 3). Recent studies have demonstrated a better efficacy of whole cell vaccine for primary immunization, as compared to acellular vaccine (Also see Chapter 23.8 on DPT vaccine).

Indian Academy of Pediatrics (IAP) recommends use of whole cell pertussis vaccine for primary immunization. WHO also recommends continuation of the whole cell pertussis vaccine in countries with limited resources.

IN A NUTSHELL

1. Pertussis is a highly communicable disease caused by *Bordetella pertussis*.
2. It is a toxin mediated disease that causes damage to the epithelium of respiratory tract, thus inhibiting clearance of secretions.
3. Clinically, disease has three stages, namely, catarrhal stage, paroxysmal stage and convalescent stage.
4. Paroxysmal stage is characterized by spasmodic cough with inspiratory whoop.
5. Infants are more likely to develop complications of the disease.
6. Diagnosis is established by isolation of organism on *Regan-Lowe* or *Bordet-Gengou* medium.
7. Management is mostly supportive, targeted towards comforting the patient and monitoring for complications.
8. Prime role of antibiotics is to render the patient noninfective and prevent the spread of the disease.
9. All the close contacts irrespective of the immunization status should be given erythromycin.
10. Immunization with 3 doses and 2 boosters of DPT vaccine prevents pertussis with 70–90% efficacy.

Chapter 29.5

Tetanus

Jaydeep Choudhury

(Also see Chapter 15.5 on Neonatal Tetanus)

Tetanus is an acute, often fatal, severe exotoxin-mediated infection caused by *Clostridium tetani*. The disease is characterized by severe muscle spasm. Rosenbach in 1886 demonstrated for the first time these slender bacilli.

EPIDEMIOLOGY

Tetanus occurs worldwide, but the incidence has reduced considerably following widespread immunization. Still it is an important preventable cause of neonatal death in developing countries. It is the only vaccine preventable disease that is infectious but not contagious from person to person. Among the burden of vaccine preventable diseases world over, tetanus ranks fourth with 13% disease burden. According to WHO in 2008, the reported cases of tetanus in India in 2006 were 2,587, of which 600 cases were of neonatal tetanus. The incidence is high in tropical countries with humid climate. More cases are reported from rural than urban areas.

ETIOLOGY

The causative organism *C. tetani* is a gram-positive, anaerobic, spore-forming organism. It forms terminal spores resembling drumsticks. The spores are resistant to boiling, usual antiseptics and chemical agents like phenol. They can survive autoclaving at 121°C for 10–15 minutes. *C. tetani* is part of the normal flora in human and animal intestines and is disseminated through the excreta. In spore form, they are hard and long-lasting in soil and dust. As the spores of *C. tetani* are ubiquitous, wound contamination is unavoidable. The contamination of wound, unhygienic and improper handling of the umbilical cord in newborns, lack of hygienic habits and aseptic care during and after delivery in women are the main risk factors for infection.

The bacilli itself is noninvasive. The spores germinate in anaerobic conditions. They produce two types of toxins—*tetanospasmin* and *tetanolysin*. Of these, tetanospasmin is a neurotoxin and is responsible for the clinical signs and symptoms of the disease. Toxins are disseminated via blood and lymphatics. Toxins act at several sites within the nervous system.

CLINICAL MANIFESTATIONS

The incubation period of tetanus is around 10 days (range 3–30 days). On the basis of clinical findings, three different forms of tetanus have been described. The most common type (80%) is generalized tetanus. *Localized tetanus* produces pain and spasm of the muscles in proximity to the site of injury. Occasionally this form of disease may precede *generalized tetanus*. *Cephalic tetanus* is a rare form of the disease seen in children with otitis media.

Generalized Tetanus

It usually presents with a descending pattern. The first sign is trismus or lockjaw due to spasm of masseter muscle, followed by stiffness of the neck, difficulty in swallowing and rigidity of abdominal muscles. The spasms can be precipitated by bright light, noise and even touch. Difficulty in swallowing, restlessness, irritability and headache are early manifestations. The rigidity of facial muscles leads to the sardonic smile of tetanus or risus sardonicus, a typical grinning appearance. Rigidity and spasm

of back and abdominal muscles causes arching (opisthotonus). Laryngeal and respiratory muscle spasm can lead to airway obstruction and asphyxia. Constipation and retention of urine may also occur. Hyperpyrexia, hypertension, excessive sweating, tachycardia and cardiac arrhythmia can occur due to sympathetic nerve involvement.

Neonatal Tetanus

It typically occurs when the umbilical cord is cut with an unsterile instrument and manifests within 3–12 days of birth. It is generalized tetanus, a serious condition and often fatal. Progressive difficulty in feeding (sucking and swallowing) with associated hunger and crying are generally seen. The baby becomes stiff and spasms develop. Opisthotonus may be extreme or sometimes absent. Neonatal tetanus has been already described in detail in Chapter 15.5.

MANAGEMENT

Diagnosis is mainly clinical. Differential diagnosis is listed in **Box 1**. The typical setting is an injured unimmunized patient or baby born to an unimmunized mother presenting within 2 weeks with trismus, rigid muscles and clear sensorium. The organism can be isolated from wound or ear discharge. The aim of therapy is to neutralize all toxins, eradication of *C. tetani* and wound environment conducive to anaerobic multiplication and supportive care.

Specific

Human tetanus immunoglobulin (TIG) 3,000–6,000 units IM is recommended to be given immediately. TIG has no effect on toxin which is already fixed to the neural tissue and does not penetrate the blood-CSF barrier. It can neutralize circulating tetanospasmin. Antitetanus serum is recommended only when TIG is not available. It can be given in a single dose of 50,000–1,00,000 units, half the dose IM and the rest IV after skin test.

Penicillin is the antibiotic of choice for *C. tetani*. Penicillin G 2,00,000 units/kg body weight can be given intravenously in four divided doses for 10–14 days. Local wound, discharging ears, umbilical cord should be cleaned and debrided.

Supportive

All patients with generalized tetanus require muscle relaxant. High-dose diazepam is preferred as it causes both muscle relaxation and seizure control. Midazolam and baclofen can also be used. Detailed management of neonatal tetanus is provided in Chapter 15.5. Almost similar principles apply for management of older children. The best survival rates with generalized tetanus are achieved with neuromuscular blocking agents like vecuronium and pancuronium. These drugs produce general flaccid paralysis, which can be managed by mechanical ventilation. Meticulous nursing care is imperative. The patient should be kept in a quiet, dark environment with minimum auditory or visual stimuli. Maintenance of nutrition, fluid and electrolyte balance, care suctioning of secretions and cardiorespiratory monitoring should be done. Provision for tracheostomy should be kept ready.

BOX 1 Differential diagnosis of tetanus

- Parapharyngeal, retropharyngeal or dental abscess—Trismus may be present
- Rabies—It may present with trismus and seizures but rabies is characterized by hydrophobia and aerophobia
- Viral encephalitis—It may present with tonic seizures but there is altered sensorium
- Hypocalcemia—It may produce tetani characterized by laryngeal and carpopedal spasms but trismus is absent.

PROGNOSIS

The average mortality of tetanus is 45–55%. For neonatal tetanus, the mortality is 60–70%. The most important factor influencing the outcome is supportive care. Recovery from tetanus does not confer immunity; therefore, active immunization of the patients following recovery is imperative.

PREVENTION

Tetanus is an entirely preventable disease. Active immunization is the best method to prevent tetanus. All children should be immunized with three doses of DPT at 6, 10 and 14 weeks followed by booster doses at 18 months and 5 years of age. Boosters should be given at 10 years and then every 10 years. Td or Tdap is the vaccine of choice above 7 years of age. Neonatal tetanus could be prevented by immunizing the pregnant women with two doses of tetanus toxoid (preferably Td) between 16 weeks and 36 weeks of pregnancy, and with only one dose of Td in the subsequent pregnancies.

Wound Management

All wounds should be cleaned, necrotic tissue and foreign material should be removed. Wounds, which are not minor, require human TIG except those in a fully immunized patient. In patients with unknown or incomplete immunization history, crush, puncture or projectile wounds, wounds contaminated with soil, saliva or feces, avulsion injuries, compound fractures, 250 U of TIG should be given IM. In cases where the wound could not be properly debrided or wound is more than 24 hours old, 500 U TIG should be given. Tetanus toxoid may be administered immediately depending on the previous immunization status of the child.

IN A NUTSHELL

1. Tetanus is an important preventable cause of neonatal death in developing countries.
2. Risk factors—Contamination of wound, unhygienic handling of the umbilical cord in newborns, lack of aseptic care during and after delivery
3. The spores germinate and produce tetanospasmin, a neurotoxin, which is responsible for the disease.
4. Difficulty in swallowing, restlessness, irritability and headache are early manifestations.
5. Laryngeal and respiratory muscle spasm can lead to airway obstruction and asphyxia.
6. Neonatal tetanus manifests within 3–12 days of birth.
7. Diagnosis is mainly clinical.
8. Human tetanus immunoglobulin (TIG) is recommended to be given immediately. Penicillin is the antibiotic of choice
9. The average mortality is 45–55%. For neonatal tetanus, the mortality is 60–70%.
10. Active immunization is the best method to prevent tetanus.

Chapter 29.6

Typhoid Fever

Apurba Ghosh, Monjori Mitra

Typhoid fever is a systemic infection with protean manifestation caused by *Salmonella enterica* serotype Typhi (*S. typhi*). Today typhoid and paratyphoid fever remain an important public health problem, mostly involving children in the younger age group and young adults than in older patients.

EPIDEMIOLOGY

The estimated incidence in year 2000 was over 21.6 million episodes of typhoid worldwide, which resulted in death of nearly 2,16,000 patients. The incidence seems to be higher in South Central Asia and Southeast Asia (more than 100 cases per 1,00,000 person-years), because of the associated poor sanitation and unsafe food and water. Other regions of Asia and Africa, Latin America, the Caribbean, and Oceania have a medium incidence of 10–100 cases per 1,00,000 person-years. The burden of enteric fever is the least well characterized in sub-Saharan Africa. Antimicrobial resistance has emerged to traditional first-line drugs, fluoroquinolones and third-generation cephalosporins, creating treatment challenges adding to the concern. Hence, globally the focus remains in the prevention of this disease by improved sanitation and vaccine. Based on this global need, development of a better immunogenic conjugate typhoid vaccine has been developed and research is being undertaken to improve further.

ETIOLOGY

Typhoid fever is caused by *Salmonella* species, which are gram-negative bacilli and belong to the family Enterobacteriaceae. Serotyping is based on the identification of serogroup antigens, the flagellar (H) antigens, and the virulence (Vi) antigen. H antigens can be either phase 1 (nonspecific) or phase 2 (specific). Reactions of *Salmonella* with antisera to specific O (somatic) antigens determine the serogroups A, B, C1, C2, D, and E and further O, H (flagellar), and Vi (capsular) antigenic characterization results in a unique serotype that traditionally has served as a surrogate species designation, e.g., *S. typhi* (now recommended). In the current scenario *S. paratyphi* A was responsible for a growing proportion of enteric fever in a number of Asian countries, sometimes accounting for 50% of *Salmonella* bloodstream isolates among patients with enteric fever.

There are six subgroups of *Salmonella* based on deoxyribonucleic acid (DNA) hybridization and most of the serotypes which are important in human and animal disease, belong to subgroup I. The examples of serotypes are: A (*S. paratyphi* A), B (*S. typhimurium*, *S. heidelberg*, *S. paratyphi* B), C1 (*S. choleraesuis*, *S. infantis*), C2 (*S. newport*), and D (*S. enteritidis*, *S. typhi*). Nontyphoidal salmonellae have emerged as a major cause of bacteremia in Africa, especially among populations with high incidence of HIV infection. These are being dealt with in the next chapter.

Salmonellae are motile, nonsporulating, nonencapsulated, Gram-negative rods that grow aerobically and are capable of facultative anaerobic growth. They are resistant to refrigeration and sometimes heating but can be killed by heating to 130°F (54.4°C) for 1 hour or 140°F (60°C) for 15 min. They remain viable at ambient or reduced temperatures for days and may survive for weeks in sewage.

TRANSMISSION

Only humans are the carriers of *S. typhi*, which is present in the bloodstream and intestinal tract. *S. typhi* is transmitted mainly by feco-oral route and the bacilli get excreted for long duration in feces and urine of cases and carriers. It spreads through fecal contaminated drinking water or food and leads to large epidemics.

It can also be associated with poor standards of hygiene in food preparation and handling leading to direct transmission of infection. The hands may be contaminated while handling patients, their excreta or infected linen. Transmission by flies is also a possibility in endemic areas.

PATHOGENESIS

Severity of the disease and the incubation period depend on the size of the inoculum, host immunocompetence, prior antibiotic use and finally the DNA sequence of the *Salmonella* strain. In some outbreaks, very small inocula of *Salmonella* seem to have caused disease. Large inocula (e.g., 10⁹ organisms) may cause severe symptoms, even in healthy children. The incubation period usually is 6–72 hours but can extend up to 14 days.

The pathogenicity depends on the multiple factors, whereby the *Salmonella* strains can adhere to, invade and multiply in intestinal epithelium; produce cholera toxin-like enterotoxin that increases cyclic adenosine monophosphate levels within intestinal crypt cells, causing a net efflux of electrolytes and water into the intestinal lumen; be taken up by M cells overlying Peyer's patches of the distal ileum and proximal colon; survive in macrophages of Peyer's patches, mesenteric lymph nodes and the extraintestinal reticuloendothelial system (RES); and survive in the bloodstream. For each of these activities, the strain specific genes encode the virulence factors necessary for each step in these processes.

After ingestion, *S. typhi* organisms invade the body through the gut mucosa in the terminal ileum, through the specialized antigen-sampling cells known as *M cells* that overlie gut-associated lymphoid tissues, through enterocytes, or via a paracellular route. *S. typhi* crosses the intestinal mucosal barrier after attachment to the microvilli by an intricate mechanism involving membrane ruffling, actin rearrangement and internalization in an intracellular vacuole. Subsequently, they cause intestinal inflammation with polymorphonuclear leukocytes and macrophages involving the lamina propria. The underlying intestinal lymphoid tissue and mesenteric lymph nodes enlarge causing interference with the blood supply to the gut mucosa and may result in small areas of necrosis. Hyperplasia of the RES is also found within the liver and spleen. If bacteremia develops, it may lead to localized infection and suppuration in almost any organ. In contrast, the pathologic findings in *S. typhimurium* and other nontyphoidal serotypes cause diffuse colitis, mucosal edema and crypt abscesses. The invasiveness of the disease depends on the virulence factor of the various *Salmonella* genes, some are shared by all strains and some are serotype-specific. Virulence plasmids have been identified in *S. typhi*, *S. typhimurium* and *S. dublin*.

Salmonella pathogenicity islands (SPI) are an important virulence factor in vivo, in particular, SPI-1 and SPI-2. Both SPIs encode a molecular apparatus called type III secretion system, capable of injecting bacterial proteins through bacterial and host membranes into host cells (translocation) or the extracellular milieu (secretion) to influence host biochemistry and cell physiology directly.

Salmonella are able to survive in macrophages but not in polymorphonuclear leukocytes. Patients with neutropenia or neutrophil dysfunction are at high risk for development of disseminated infection. Cytokines play a crucial role in initiating and regulating the innate and adaptive immune response against

Salmonella. These bacteria can trigger synthesis of cytokines and chemokines in epithelial cells, macrophages and dendritic cells. The consequences of cytokine activation vary and at times with impaired immunity, there may be severe bacteremia following *Salmonella* infection.

Children with sickle-cell and S-Thal also sometimes develop osteomyelitis. Malaria predisposes to salmonellosis by multiple mechanisms. Schistosomiasis predisposes to development of *Salmonella* infections and prolonged bacteremia.

CLINICAL FEATURES

The mean age at onset of typhoid was 8.5 years for the site in Pakistan, 10.0 years in India, 10.2 years in Indonesia, 10.5 years in Vietnam and 12 years in China. The incubation period of typhoid fever is usually 4–14 days but depends on the infecting dose and ranges between 3 days and 30 days. The onset is insidious and varies from a mild illness with low-grade fever, malaise, and slight dry cough to a severe clinical picture with abdominal discomfort and multiple complications. The majority of patients with typhoid fever present with abdominal pain, fevers and chills. Children commonly complain of headache; they often are drowsy, irritable or delirious. Mild arthralgia involving multiple joints and vague, poorly localized back pain occur in nearly 60% of patients.

Classic reports described the characteristic stages of typhoid fever in untreated individuals. In the first week of illness, rising (*stepwise*) fever and bacteremia develop. While chills are typical, frank rigors are rare. Relative bradycardia or pulse-temperature dissociation may be observed. The patient has a dull, expressionless, toxic facies; coated tongue; a musty, *damp hay-like* odor; and a tender, doughy abdomen with slight guarding. Occasionally, a child may have a cough; it tends to be minimal and unimpressive. The skin is dry with little sweating. Meningismus may occur early in the illness.

In the 2nd week of illness, abdominal pain develops and *rose spots* (faint salmon-colored macules on the trunk and abdomen) may be seen. A soft, tender spleen is palpable, respiratory symptoms may progress, and epistaxis occasionally may occur. If untreated, typhoid fever has a prolonged course, with continuous high temperature of 39.5–40.5°C for up to 4 weeks, followed by a gradual return to normal, beginning during the 3rd or 4th week.

During the 3rd week of illness, hepatosplenomegaly, intestinal bleeding and perforation due to ileocecal lymphatic hyperplasia of the Peyer's patches may occur, together with secondary bacteremia and peritonitis. Septic shock or an altered level of consciousness may develop. In the absence of acute complications or death from overwhelming sepsis, symptoms gradually resolve over weeks to months.

Constipation occurs with approximately equal frequency but diarrhea may be more common, particularly in young children. When diarrhea develops, it usually does so after the patient has been febrile for several days. It is small in volume, resembles pea soup, and contains erythrocytes but usually is not grossly bloody. Fecal leukocytes are present in nearly all patients with diarrhea. Diarrhea occurs more commonly with paratyphoid than with typhoid fever.

Vomiting is mild and not sustained. Among 552 patients with culture-confirmed typhoid fever in Bangladesh, abdominal tenderness or distension (57%) and rectal bleeding (9%) were equally distributed across age groups. Headache is a frequent symptom reported in 44–94% of cases. Cough is not rare and has been observed in approximately 20–45%; arthralgia and myalgia occur in about 20%.

The clinical features of enteric fever in **Table 1** were observed in a study from India.

Table 1 Clinical features of enteric fever in India

Clinical findings	%
Fever > 38.4°C	100
Headache	67.8
Constipation/diarrhea	55.9
Poor appetite	35.7
Abdominal pain	63.3
Splenomegaly	24.7
Hepatomegaly	66.9

COMPLICATIONS

Complications occur in 10–15% of patients; most of these develop during the 2nd or 3rd week of illness. Although altered liver function is found in many patients with enteric fever, clinically significant hepatitis, jaundice and cholecystitis are relatively rare and may be associated with higher rates of adverse outcome. Intestinal perforation generally occurs more frequently among adults than children and is associated with high mortality rates.

Patients with severe typhoid fever may develop *typhoid encephalopathy*, with altered consciousness, delirium, and confusion, myelitis, acute cerebellar ataxia, chorea, deafness, and Guillain-Barré syndrome. Although case fatality rates may be higher with neurologic manifestations, recovery usually occurs with no sequelae. Other reported complications include fatal bone marrow necrosis, disseminated intravascular coagulation (DIC), hemolytic-uremic syndrome, pyelonephritis, nephrotic syndrome, meningitis, endocarditis, parotitis, orchitis and suppurative lymphadenitis.

Individuals who excrete *S. typhi* for more than or equal to 3 months after infection are regarded as chronic carriers. The risk for becoming a carrier is low in children (< 2% for all infected children) and increases with age. A chronic urinary carrier state can develop in children with schistosomiasis.

DIAGNOSIS

The mainstay of the diagnosis of typhoid fever is a positive result of blood culture. Blood cultures are positive in 40–80% of patients, depending upon the series and culture techniques used. The diagnosis can also be made by culture of stool, urine, rose spots, or duodenal contents (via string capsule). However, the sensitivity of blood cultures in diagnosing typhoid fever in many parts of the developing world is limited because widespread liberal antibiotic use may render bacteriologic confirmation difficult. Bone marrow cultures may be positive in as many as 50% of patients after as many as 5 days of antibiotics although bone marrow cultures may increase the likelihood of bacteriologic confirmation of typhoid, collection of the specimens is difficult and relatively invasive and hence not routinely practiced.

S. typhi isolates should be screened for resistance to nalidixic acid, or have formal sensitivity testing for the clinically used fluoroquinolones. Nalidixic acid resistant *Salmonella typhi* (NARST) should be anticipated to have reduced susceptibility to fluoroquinolones, even if the laboratory reports fluoroquinolone sensitivity.

Patients with typhoid fever frequently have anemia and either leukopenia or leukocytosis. Leukopenia with left shift is typically seen in adults while leukocytosis is more common in children. If observed in the 3rd week of illness, leukocytosis should prompt suspicion for intestinal perforation. Thrombocytopenia may be a marker of severe illness and may accompany DIC. Liver

function test results may be deranged, but significant hepatic dysfunction is rare. Cerebrospinal fluid studies are usually normal or reveal a mild pleocytosis (< 35 cells/mm³), even in patients with neuropsychiatric symptoms.

Serologic tests such as the Widal test are of limited clinical utility in endemic areas because positive results may represent previous infection. Positive results have been reported in 46–94% of cases. Because many false-positive and false-negative results occur, diagnosis of typhoid fever by Widal test alone is prone to error. Other relatively newer diagnostic tests using monoclonal antibodies have been developed that directly detect *S. typhi* specific antigens in the serum or *S. typhi* Vi antigen in the urine. A nested polymerase chain reaction analysis using *H1-d* primers has been used to amplify specific genes of *S. typhi* in the blood of patients; it is a promising means of making a rapid diagnosis, especially given the low level of bacteremia in enteric fever.

Newer serologic assays, Typhidot, using enzyme-linked immunosorbent assay (ELISA) and dipstick techniques perform somewhat better than the Widal test, but sensitivity and specificity are not adequate for routine diagnostic use. An ELISA for antibodies to the capsular polysaccharide Vi antigen is useful for detection of carriers, but not for the diagnosis of acute illness.

TREATMENT

With the emergence of multidrug resistance of *S. typhi* to the first-line drugs ampicillin, chloramphenicol, and trimethoprim-sulfamethoxazole in the 1990s, the treatment of typhoid was shifted to the quinolones and third generation cephalosporin. The intracellular site of *Salmonella* has favored the use of fluoroquinolones because of the theoretical advantage. In recent years, development of increasing resistance to fluoroquinolones has resulted in more challenges.

Resistance patterns have led to a shift toward the third generation cephalosporins, azithromycin and fluoroquinolones as empiric therapy for typhoid fever while awaiting the results of antimicrobial susceptibilities. With the development of fluoroquinolones resistance, third generation cephalosporins were used in treatment but sporadic reports of resistance to these antibiotics also followed. Recently, azithromycin is being used as an alternative agent for treatment of uncomplicated typhoid fever.

As per the guidelines developed by Indian Academy of Pediatrics for management of enteric fever, cefixime is the drug of choice for uncomplicated typhoid and third generation parenteral cephalosporins (ceftriaxone or cefotaxime) are drug of choice for severe typhoid. Aztreonam and imipenem may also be used as second line drugs (**Tables 2 and 3**). Fluoroquinolones can be used in life-threatening infections resistant to other recommended antibiotics.

Reports by elegant molecular studies have documented MDR clones of *S. typhi* in Africa and Asia that now account for many (85%–100% of outbreak strains in Kenya) isolates. These patterns of resistance appear to be shifting with changing pressures in antimicrobial use. Fluoroquinolone-resistant *S. paratyphi* A is an emerging problem in India and Nepal as fluoroquinolone use has flourished. Despite a steady rise in resistance in most studies, re-emergence of strains susceptible to first-line antimicrobial agents, including ampicillin, chloramphenicol and cotrimoxazole, has been reported.

Duration of therapy depends on serotype and site of infection. Ceftriaxone is the best initial parenteral choice because of widespread resistance to other agents. For susceptible strains, ampicillin, trimethoprim-sulfamethoxazole and chloramphenicol have all been used successfully, and fluoroquinolones have been used extensively, even in children in endemic areas.

Therapy usually is continued for 10–14 days in children, for 4–6 weeks for acute osteomyelitis and for 4 weeks for meningitis. In the developing world, *Salmonella* infection associated with schistosomiasis requires treatment of both infections to achieve resolution.

Defervescence in typhoid fever usually requires at least 36 hours of therapy and fever can persist for 5–7 days, even with ultimately effective therapy. Azithromycin has been effective in children with strains resistant to first-line agents.

Corticosteroids are used as adjunctive therapy in the presence of delirium, obtundation, stupor, coma, or shock in children with typhoid fever; a dose of 3 mg/kg dexamethasone initially, followed by 1 mg/kg every 6 hours for 48 hours, was associated with reduction of mortality from, between 35% and 55% to 10%. For patients in whom intestinal perforation develops, surgery coupled with broad-spectrum antimicrobial therapy directed at anaerobic and gram-negative enteric bacteria is indicated. The mortality after perforation can be as high as 10–30%.

Relapse

Relapse was considered with the recurrence of clinical disease, culture-proven infection with *Salmonella typhi* and *paratyphi* isolates (as described earlier), and with an antibiogram identical to the original isolates, within 8 weeks of cessation of successful therapy of the initial infection. **Table 4** depicts the rate of relapse in NARST infections. The relapse rate also varies with the antibiotic used for the initial treatment, though insufficient data, but it shows least rate of relapse with azithromycin and ofloxacin high dose.

The relapse rate is associated with various factors. Treatment of multidrug resistance (MDR) enteric fever with quinolones may be predicted to better eradicate *Salmonella* from the RES than treatment with first-line antimicrobials. Infection for greater than 14

Table 2 Treatment of uncomplicated typhoid fever

Susceptibility	First-line oral drug			Second-line oral drug		
	Antibiotic	Daily dose (mg/kg)	Days	Antibiotic	Daily dose (mg/kg)	Days
Fully sensitive	3rd gen. cephalosporin e.g., Cefixime	15–20	14	Chloramphenicol Amoxicillin Trimethoprim-Sulfamethoxazole (TMP-SMX)	50–75 75–100 8–TMP 40–SMX	14–21 14 14
Multidrug resistant	3rd gen. cephalosporin e.g., Cefixime	15–20	14	Azithromycin	10–20	7

Table 3 Treatment of severe typhoid

Susceptibility	First-line parenteral drug			Second-line parenteral drug		
	Antibiotic	Daily dose (mg/kg)	Days	Antibiotic	Daily dose (mg/kg)	Days
Fully sensitive	Ceftriaxone	50–75	14	Chloramphenicol	100	14–21
	Or			Ampicillin	100	14
	Cefotaxime			Trimethoprim-Sulfamethoxazole (TMP-SMX)	8-TMP 40-SMX	14
Multidrug resistant	Ceftriaxone	50–75	14	Aztreonam	50–100	14
	Or Cefotaxime					

Table 4 Rate of relapse in nalidixic acid resistant *Salmonella typhi* (NARST) infection

Drug	Dosage	Fever clearance time (Median or mean)	Rate of treatment failure	Relapse rate
Azithromycin	10–20 mg/kg od × 7d	4.4d	9%	< 1%; insufficient data
Cefixime	10 mg/kg bid × 7d	5.8d	27%	9%
Ceftriaxone	60–75 mg/kg qid × 10–14d	6.1d	9%	5%

days prior to therapy may lead to a greater immune system activation thereby allowing improved *Salmonella* clearance from the RES. Likewise, as this organism is shed through the stool, it is possible that constipation may lead to a higher load of organism within the body whereas diarrhea could be predicted to cause the opposite effect.

Despite appropriate therapy, 2–4% of infected children may experience relapse after initial clinical response to treatment. The same therapy should be repeated with proper dose and duration after sending culture. In case the empiric antibiotic is not sensitive, then it should be changed to appropriate sensitive antibiotic and the total duration should be based on the antibiotic type.

PREVENTION

The prevention of typhoid fever should focus on the control of the infection in the animal reservoir; prevent contaminated foods prepared from animals, and improvement in personal hygiene, sewerage and drinking water supply. Clean water supply, education in hand-washing, and food preparation and storage are critical to reducing person-to-person transmission. *Salmonella* may remain viable when cooking practices prevent food from reaching a temperature greater than 150°F (65.5°C) for more than 12 minutes.

Two safe and efficacious typhoid vaccines, the injectable Vi polysaccharide and the oral Ty21a, had been licensed but the oral vaccine due to its own limitation has not been used widely in the developing countries and is not available in India. Currently the new, improved typhoid conjugate vaccines are being tested and recently marketed in India. The Vi polysaccharide subunit vaccine was first licensed in the United States in 1994. It is composed of purified Vi capsular polysaccharide from the Ty2 *S. typhi* strain and elicits a T-cell-independent IgG response that is not boosted by additional doses. The vaccine is administered subcutaneously or intramuscularly. The Vi vaccine does not elicit adequate immune responses in children aged below 2 years. Several large field trials suggest that the Vi capsular vaccine as a single 25-μg dose (0.5 mL) has an efficacy of 55–75% in adults and children older than 5 years. Conjugate vaccines are also available now for those below 2 years of age. Detailed discussion on typhoid vaccines is available in Section 23.

IN A NUTSHELL

1. Typhoid fever is the commonest bacterial infection in the developing countries. In the developed countries, it is mostly because of the travelers.
2. The infection depends on the size of the inoculum, use of prior antibiotic, prevailing of the MDR strains and the DNA sequence of the organism.
3. There is an increasing surge of the paratyphi infection and is mostly because of the infection related to the poultry products.
4. The clinical features have an insidious onset with high rise of fever, headache, abdominal discomfort, both diarrhea and constipation and hepatosplenomegaly.
5. Complications of typhoid are seen in 10–15% with intestinal perforation and bleeding being the most serious in nature.
6. BACTEC culture positive is the gold standard ranging from 40–80% positivity. Serology though not specific but in late presentation can be an evidence of diagnosing with strong clinical suspicion, particularly with rising titer.
7. The first-line treatment for MDR typhoid is 3rd generation cephalosporins and quinolones, and the duration should be 14 days. But recently it has been seen that the quinolones are becoming resistant and the MIC of cephalosporin is increasing. Studies have shown azithromycin in the dose of 20 mg/kg for 5–7 days has a good efficacy.
8. Relapse of typhoid when occurs must be treated with the same drug as before unless the sensitivity report shows a different result and is continued for 14 days.
9. Prevention of typhoid has to be with improvement in the sanitation and good supply of drinking water.
10. Ultimately it has become a global concern to prevent typhoid by effective vaccine.

Chapter 29.7

Nontyphoidal Salmonellosis

Thangavelu Sangaralingam, Janani Ravi

There are two forms of clinical expression of *Salmonella* infection: (1) Typhoid or paratyphoid fever caused by *Salmonella typhi* and *paratyphi*; and (2) *Salmonella enterocolitis* (including food poisoning) which may be complicated by bacteremia and/or focal suppurative complications, such as enteritis, cholecystitis, meningitis, arthritis, osteomyelitis, pneumonia and empyema. These organisms leading to the second presentation other than typhoid and paratyphoid are known as nontyphoidal salmonellosis. *S. enterica* is the new terminology and it has 2,500 serotypes. Among these, five serotypes are important (**Table 1**). *S. typhimurium* and *S. enteritidis* are most commonly incriminated in nontyphoidal salmonellosis.

EPIDEMIOLOGY

Nontyphoidal salmonellosis (NTS) is increasingly being reported in every country following consumption of common food preparations, such as animal products and eggs. The commonly affected age group is less than 5 years old with a peak between 6 months and 2 years. The disease is prevalent not only in humans but also in pet animals, livestock and poultry which act as reservoirs and continue to pose threat to humans. Studies on isolation of *Salmonella* from diarrhea stools in both humans and animals done in the Northeastern part of India showed that 14.4% of isolates in animals and 20% of stool samples in human beings isolated *Salmonella* serovars. Out of 13 million cases with nontyphoidal salmonellosis reported worldwide, about 70% are reported from three countries, India, China and Pakistan. The single largest reservoir of *Salmonella* is constituted by poultry. Many of the *Salmonella* strains are also developing resistance to common antimicrobials.

MICROBIOLOGY AND MODE OF SPREAD

Salmonella are gram-negative motile organisms with more than 2,500 serovars or serotypes. According to the current nomenclature, *S. enterica* is the common (single) name for all the medically important *Salmonella*. Three serotypes, namely *S. enteritidis* (39%), *S. typhimurium* (20%) and *S. newport* (9%) constitute more than half of the *Salmonella* infections isolated in humans in the United States. Prime reservoirs of NTS are poultry, livestock, reptiles and pets. The vehicles of transmission are food products of animal origin, like poultry, beef, eggs and dairy products. Other vehicles implicated are: vegetarian products contaminated with infected human or animal source, such as fruits, vegetables, peanut butter, frozen pot pies, powdered infant formulas, cereals and bakery products (**Table 2**). Predisposing factors for the development of salmonella infections are listed in **Table 3**.

Majority of nontyphoidal salmonellae are nonhost adapted (not host-specific) and hence have the potential to affect both human and animals. Three serovars, *S. typhi*, *S. typhimurium* and *S. paratyphi* play a prominent role in human infection.

CLINICAL FEATURES

Various clinical categories of *Salmonella* infections are acute gastroenteritis, bacteremia and focal infections (meningitis, pneumonia, arthritis, osteomyelitis, etc.). These are not discrete entities but form a clinical spectrum (**Table 4**).

Salmonella Gastroenteritis/Food Poisoning

The usual presentation is fever, nausea, headache, diarrhea with abdominal pain; *Salmonella* diarrhea cannot be clinically differentiated from other bacterial pathogens. Symptoms of food poisoning generally develop in 12–36 hours (range 6–72 hours) after the consumption depending on the amount of inoculum and host response. *Salmonella* gastroenteritis is a self-limiting illness: fever subsides by 48–72 hours and diarrhea resolves by 4–10 days. Most of the milder cases are not even recognized.

Salmonella Bacteremia

Bacteremia is a serious complication of *Salmonella* infection and believed to occur in 1–5% of the children with *Salmonella* diarrhea. Unlike in adults where 90% had underlying predisposing factors, majority of the children with *Salmonella* bacteremia were previously healthy. Organism and serotypes commonly involved are *S. enteritidis* and *S. typhimurium* and less commonly implicated serotypes are *dublin*, *choleraesuis*, *virchow*, *infantis* and *heidelberg*. The infection may spread to various organs resulting in arthritis, osteomyelitis, pneumonia, endocarditis, mycotic aneurysm and meningitis. Increased risk of bacteremia is associated with three species: *S. typhimurium*, *S. choleraesuis* and *S. heidelberg*.

Clinical Presentation

Predominant features of *Salmonella* bacteremia are fever, tachypnea and diarrhea. Out of 229 children with *Salmonella* bacteremia, 69% had respiratory symptoms and diarrhea. Pneumonia was present in 20.5% of the cases. As they fulfill the World Health Organization (WHO) criteria for pneumonia, there is a possibility of being treated for isolated pneumonia with penicillin and not with appropriate antibiotics for NTS. In children, 75% of the bacteremia were secondary to gastroenteritis and there was no death. However, in majority of the adults, bacteremia was primary and mortality was high amounting to 33%. In a retrospective study done in a pediatric hospital, 12 out of 144 children with bacteremia developed focal infection as complication.

Salmonella Meningitis

This is more commonly seen in neonates and infants, and more than three-fourths of the children affected were less than 1-year-old in most of the studies. *S. enteritidis* is the commonly incriminated organism reported and rarely *S. typhimurium*.

Table 1 Nomenclature for *Salmonella* organisms

Complete name	CDC designation	Commonly used name
<i>S. enterica</i> subspecies <i>enterica</i> serotype <i>typhi</i>	<i>S. ser. Typhi</i>	<i>S. typhi</i>
<i>S. enterica</i> subspecies <i>enterica</i> serotype <i>typhimurium</i>	<i>S. ser. Typhimurium</i>	<i>S. typhimurium</i>
<i>S. enterica</i> subspecies <i>enterica</i> serotype <i>newport</i>	<i>S. ser. Newport</i>	<i>S. newport</i>
<i>S. enterica</i> subspecies <i>enterica</i> serotype <i>choleraesuis</i>	<i>S. ser. Choleraesuis</i>	<i>S. choleraesuis</i>
<i>S. enterica</i> subspecies <i>enterica</i> serotype <i>enteritidis</i>	<i>S. ser. Enteritidis</i>	<i>S. enteritidis</i>

S. typhimurium will be called *Salmonella enterica*, serotype *Typhimurium*.

Table 2 Mode of infection of *Salmonella* infections

Mode of infection	Sources
Foodborne: animal origin	Undercooked eggs, or eggs showing no external evidence of infection or rotting, cheese, dry cereals, ice-cream premix
Other food vehicles	Fresh sprouts, peanut butter, frozen pot pies, juice, cantaloupes, bakery products, hot water-treated mangoes and fresh vegetables
Ingestion of contaminated water	Reptiles and birds
Contact with infected reptiles and amphibians	Pet turtles, lizards, snakes, frogs, toads, rodents
Nosocomial transmission	In the hospital from the affected child through stool or urine contamination; contaminated instruments, drugs and solutions

Table 3 Predisposing factors for GI salmonellosis and its sequelae

Factors	Affected population
Gastric hypoacidity	Infancy, use of H ₂ blockers and antacids
Extremes of age	
Alteration of endogenous flora	Antimicrobial therapy, surgery
Systemic diseases	Diabetes, rheumatological disorders, malignancy
Reticuloendothelial blockade	Sickle cell disease, malaria
Immunosuppression	HIV, immune deficiency, therapeutic immunosuppression, steroids
Anatomical disruption	Kidney stones, abnormalities of urinary tract, gall stones, prosthesis

Table 4 Clinical spectrum of *Salmonella* infection

Typhoid fever Caused by <i>S. typhi</i> or <i>paratyphi</i> A or B, this infection leads to systemic illness usually with little or no diarrhea. These organisms are highly adapted for humans. They do not cause colonization or disease in animals and are transmitted via fecal contaminated water or food items from an acutely affected human.
Nontyphoidal <i>Salmonella</i> This disease predominantly presents as diarrheal disease following consumption of food contaminated by animal or human fecal material. <i>S. typhimurium</i> and <i>enteritidis</i> cause gastroenteritis in children, but <i>S. choleraesuis</i> and <i>S. dublin</i> are associated with bacteremia and metastatic foci in humans. These organisms are nonadapted and hence cause diseases in human as well as animals.
• Enteritis
• Septicemia
• Localization: Meningitis, septic arthritis, osteomyelitis, cholangitis, pneumonia, endocarditis, mycotic aneurysm.

meningitis. These are rare causes of meningitis, constituting less than 1% of all causes of meningitis in neonates and infants. This is often associated with high mortality and morbidity. Both acute and chronic complications like neurodevelopmental sequelae, such as paralysis, deafness, seizures, visual disturbances and mental retardation are also more commonly encountered. Clinical presentation is similar to that of any other bacterial meningitis. It is more commonly suspected if the mother has suffered earlier from a salmonella infection and she remains as a carrier.

DIFFERENTIAL DIAGNOSIS

Escherichia coli, *Shigella*, *Campylobacter jejuni* and *Vibrio cholerae* are the common pathogens constituting bacterial etiology in acute diarrhea. Presence of blood in the stools usually favors the diagnosis of enterohemorrhagic *E. coli* or *Shigella*. In cases of suspected food poisoning, consumption of the food item is related to an individual or group of individuals, and time of onset of symptoms will be helpful to arrive at a diagnosis. In staphylococcal food poisoning, symptoms develop within 6 hours, but in *Salmonella*, the time gap will be a little later than 12–36 hours.

LABORATORY INVESTIGATIONS

In *Salmonella* gastroenteritis, stool microscopy may reveal the presence of pus cells. Fresh stools are ideal for culturing *Salmonella*. Stool culture is preferable in comparison with rectal swab because of higher specificity and sensitivity. Blood culture is positive if bacteremia is suspected. Other investigations such as imaging of bone or joint with bone scan are needed when child develops arthritis or osteomyelitis. MR imaging of the brain with CSF analysis is mandatory in salmonella meningitis.

Presence of neutrophils, low glucose and high protein in the cerebrospinal fluid (CSF) and additional presence of gram-negative bacilli is suggestive of *Salmonella* meningitis. Neuroimaging is a useful tool to identify the acute complications, such as subdural effusion, empyema, ventriculitis, hydrocephalus, abscess and intracranial hemorrhage. Blood, stool and urine culture may isolate *Salmonella* in cases with bacteremia.

MANAGEMENT

Salmonella Enterocolitis

Salmonella gastroenteritis is a self-limiting illness and the diarrhea is expected to be controlled within a period of 4–10 days. Management is mainly supportive using appropriate fluid and electrolyte therapy. Antibiotic therapy is not warranted in an uncomplicated child with *Salmonella* diarrhea and is rather supposed to prolong the duration of illness and fecal excretion rate. Hence, it is not recommended in general. However, the Center for Disease Control and Prevention (CDC) in the United States recommends antimicrobial therapy only for a selective category of children where there is increased risk of invasive infection—children younger than 3 months of age, those with chronic gastrointestinal disease, malignancy, hemoglobinopathies, HIV infection, immunosuppressive therapy or illnesses. Ampicillin, amoxicillin or co-trimoxazole is recommended in susceptible strains. In areas with high rate of antimicrobial resistance, third-generation cephalosporins and fluoroquinolones are the preferred choice. Duration of therapy is 5–7 days.

Salmonella Bacteremia

When *Salmonella* sepsis is suspected, infants less than 3 months and children with stool culture positivity should be hospitalized. Evaluation should be done to identify focal infections, like meningitis, osteomyelitis or arthritis. For invasive but nonfocal infection like bacteremia, usually the initial antibiotic is third-generation cephalosporin or quinolone for a period of 14 days. Most of the papers published prior to 2,000 showed poor outcome and high morbidity when these patients were treated with chloramphenicol and ampicillin. Availability of third-generation cephalosporins and fluoroquinolones has changed the outcome because of their higher efficacy.

Salmonella Meningitis

The ideal empirical antibiotic therapy in salmonella meningitis is ceftriaxone or cefotaxime alone or with a combination of third

generation along with quinolones. Alternative drugs in critically ill children are meropenem 120 mg/kg/day in 3 divided doses or cefepime 150 mg/kg/day in 3 divided doses, and later adjusted according to the sensitivity pattern. Generally, ceftriaxone is used for 4–6 weeks to complete the therapy. The commonly used empirical antibiotic combination in any young infant with meningitis, prior to microbiological diagnosis is ceftriaxone and gentamicin and will not be effective against *Salmonella* meningitis. Hence, a diagnosis of *Salmonella* meningitis should be suspected prior to obtaining cultures by the presence of gram-negative bacilli in the CSF by Gram stain, or culture growing gram-negative bacilli from any other specimen like blood or urine in a child with bacterial meningitis.

As per the British Society of Antimicrobial Therapy, duration of therapy should be for a minimum period of 3 weeks from the first sterile CSF, and CSF analysis should be done not earlier than 4 days of therapy. Recent reports indicate that ciprofloxacin causing arthropathy is extremely uncommon and the treatment of serious infection should definitely outweigh the risk. In neonates, cefotaxime is the right choice rather than ceftriaxone for the fear of bilirubin encephalopathy. When cefotaxime is used, it should be given in high doses of 200–300 mg/kg/day. The whole course should be given through intravenous route. As relapse is a potential problem, even after good clinical recovery, the child should be monitored vigilantly. At earliest evidence of relapse, the same drug combination can be restarted as the relapse is due to intracellular localization of the organism and insufficient penetration of the antibiotics. Of course, the duration of therapy will definitely have to be longer than the first therapy and should be modified by the clinical response in CSF.

PROGNOSIS

Prognosis is good in *Salmonella* gastroenteritis. In *Salmonella* bacteremia without focal complications, prognosis is good with antibiotic therapy for 10–14 days. Prognosis is guarded in focal infections. In *Salmonella* meningitis, the fatality rate, acute complication, relapse and later sequelae are high.

PREVENTION

As long as there is fecal or urinary excretion, there is a risk of transmission. In children younger than 5 years, 45% of them continue to excrete organisms in the feces even beyond 12 weeks, keeping the school or household contacts at risk. During this period, diaper and urine-soaked clothes should be properly

disposed. People handling food should be exempted from the work till they stop excretion of organisms. Eggs and other foods of animal origin should be cooked properly and raw egg or partially cooked egg consumption should be discouraged. Ultimately, proper hand hygiene is the best method that prevents transmission.

IN A NUTSHELL

1. Nontyphoidal salmonellosis is equally common like typhoid disease.
2. Suspect NTS when the child has features of enterocolitis without blood in the stools. Ordering for stool culture in appropriate circumstances will help in the diagnosis.
3. *Salmonella* bacteremia may resemble pneumonia. If atypical features like diarrhea, follow-up the blood culture for gram-negative bacilli.
4. Suspect NTS meningitis in early part of the disease when Gram stain showed gram-negative bacilli. It needs a broad coverage for longer period and careful monitoring for relapse.
5. Complications are more in *Salmonella* meningitis and need neuroimaging and early management of complication.
6. Prevention is possible with hygienic food handling and time-tested handwashing.

Chapter 29.8

Haemophilus influenzae B Infections

Somu Sivabalan

Haemophilus influenzae is a pleomorphic gram-negative, facultative anaerobic coccobacillus that was first described during influenza pandemic by Richard Pfeiffer in 1892. Until 1933, this organism was mistakenly considered to be the cause of influenza till the viral etiology was identified. Yet in practice, the term *bacterial influenza* persists to exist. There are six identifiable typeable encapsulated (a, b, c, d, e and f) and nontypeable unencapsulated *Haemophilus influenzae* causing infections in children. The encapsulated serotypes have their distinct capsular polysaccharides. *Haemophilus* is responsible for a wide range of localized and invasive infections. *Haemophilus influenzae* type b (Hib) accounts for over 90% of serious infections with significant morbidity and mortality in infants and children younger than 5 years of age.

EPIDEMIOLOGY

In the year 2000, the World Health Organization (WHO) estimated that globally Hib caused over 8 million cases of serious disease and 376,000 deaths. Pneumonia and meningitis comprise the majority of the severe diseases caused by Hib in developing countries. Countries using Hib vaccine in national immunization programs have virtually eliminated Hib disease; however, Hib disease continues to occur in countries that do not use Hib vaccines widely. Studies have demonstrated a high burden of Hib disease in South and Southeast Asia.

It is believed and suggested that Hib disease is uncommon in Asia, largely due to unavailability of epidemiological data. In India, available data on Hib diseases indicates that Hib is one of the leading causes of meningitis and pneumonia in children less than 5-year-old. According to the WHO estimates, 2.4–3.0 million cases of Hib disease occur annually in the country with total deaths estimated to be at 72,000. During 1993–1997, a Prospective Surveillance Study and Review of acute Hib infections by Invasive Bacterial Infections Surveillance (IBIS) group of the International Clinical Epidemiology Network in 6 academic referral hospitals revealed significant disease burden, with substantial morbidity, mortality and drug resistance in children less than 5 years of age. This data also suggested universal immunization with available Hib vaccines will definitely benefit Indian children. Data revealed Hib contributes 40–50% of all meningitis and 25–30% of all pneumonia cases. Hib is the most common cause of meningitis and the second largest cause of pneumonia (after *Streptococcus pneumoniae*) in India. The case fatality ratio for the Hib meningitis and pneumonia is in the range of 10–30%. In addition to mortality, Hib causes a substantial morbidity burden with 25–30% of Hib meningitis survivors suffering from long-term neurological sequelae. It is estimated that mortality due to Hib disease contributes 4% of all annual under-5 deaths in India. The introduction of liquid pentavalent vaccine (LPV) in India having antigens of DPT, hepatitis B, and Hib is a major step forward to accelerate child survival in India.

TRANSMISSION

Hib spreads either by direct person to person contact or through respiratory droplets by coughing and sneezing. Most strains of *Haemophilus influenzae* bacteria, including Hib, are usual

commensals in upper respiratory flora and are harmless. They can cause noninvasive infection, like bronchitis, pneumonia or ear infection, by contiguous spread. In noninvasive form, disease is usually nonsevere and complications are rare with appropriate antibiotics. Sometimes, the bacteria can enter the blood and spread, causing serious invasive disease that can be serious or fatal. Most of the time, they are spread through asymptomatic people. The incubation period could be as short as a few days. The risk of transmission increases when children spend prolonged periods of time together in settings such as day-care or crèches. Children are often asymptomatic carriers of the Hib bacteria showing no signs or symptoms but still can infect others.

CLINICAL FEATURES

The most common manifestations of invasive *Haemophilus influenzae* disease are bacteremia (septicemia), meningitis, invasive pneumonia (through bloodstream), epiglottitis, cellulitis, infectious arthritis, and osteomyelitis or septic arthritis. Less common infections include endocarditis, endophthalmitis, peritonitis and gangrene. The disease occurs primarily in children aged less than 2 years, particularly in infants. Children between the ages of 4–18 months of age are most at risk. At birth, antibodies from the mother sufficiently protect most infants. When the child reaches 2 or 3 months of age, the level of maternal antibodies decreases and the risk of Hib infections increases. By the age 5 years, most children will have already developed their own immunity against Hib. Children with following medical conditions are at higher risk for developing a Hib infection: sickle cell disease; asplenia (no spleen); HIV infection; antibody and complement deficiency syndromes; and recipients of chemotherapy, radiation therapy for malignant neoplasms, and hematopoietic stem cell transplants.

COMPLICATIONS

Overall mortality from Hib meningitis is approximately 5%. Morbidity includes neurologic sequelae, like partial-to-total sensorineural hearing loss, developmental delay, language delay, behavioral abnormalities, language disorders, impaired vision, mental retardation, motor problems, ataxia, seizures and hydrocephalus. Approximately 6% of individuals with Hib meningitis experience permanent sensorineural hearing loss. Epiglottitis carries a mortality of 5–10% secondary to acute respiratory tract obstruction. Invasive neonatal disease carries a mortality rate of 55%.

DIAGNOSIS

The diagnosis of Hib disease can be made by bacterial culture, latex agglutination test or by polymerase chain reaction (PCR). It is very difficult to identify Hib in resource poor settings. The bacterial culture of CSF, blood, synovial, pleural, pericardial or peritoneal fluid is recommended. Gram stain of infected body fluids can facilitate presumptive diagnosis.

TREATMENT

Initial therapy for possible Hib meningitis and other invasive disease is either with intravenous *ceftriaxone* 100 mg/kg/24 hours OD/Q 12 hours. Max: 2 g/dose and 4 g/24 hours or *cefotaxime* 100–200 mg/kg/24 hours Q 6–8 hours IV. Meningitis dosage: 200 mg/kg/24 hours Q 6–8 hours. Max: 12 g/24 hours. *Ampicillin* (100–200 mg/kg/24 hours Q 6–8 h IV; severe infection 200–400 mg/kg IV every 4–6 hours, max 8 g/24 hours) could be used if isolate shows sensitive pattern. Therapy is at least for 10 days or longer in complicating infections. *Meropenem* (120 mg/kg/24 hours or 40 mg/kg IV Q 8 hours IV, max 6 g/24 hours) is an alternate empiric agent in drug resistant cases. *Dexamethasone* (0.4 mg/kg Q 12 hours IV for 2 days or 0.15 mg/kg Q 6 hours for 4 days) is beneficial in diminishing the risk of hearing loss

if given before or concurrently with the first dose of antimicrobials. In epiglottitis, airway should be secured by endotracheal tube or tracheostomy in addition to antimicrobials. In infected pleural or pericardial collections, the fluid should be drained. Treatment is not always effective because some strains may be resistant to antibiotics. Isolates produce beta-lactamase necessitating beta-lactamase resistant agent. Antibiotic resistance is a serious problem, which is continuously increasing in developing countries, including India.

CONTROL MEASURES

These are measures undertaken to control the risk and spread of Hib infection. These include: (1) Isolation of index case patients with invasive Hib disease: droplet precautions are recommended for 24 hours after initiation of effective antimicrobial therapy; (2) care of the exposed people: careful observation of exposed, unimmunized or incompletely immunized children who are in household, child care or nursery school contact of patients with invasive Hib disease is essential (**Flow chart 1**). Exposed children in whom febrile illness develops should receive prompt medical evaluation. Household contact is defined as people who reside with the index patient or nonresidents who spent 4 or more hours with the index patient for at least 5 of the 7 days preceding the day of hospital admission of the index case; (3) chemoprophylaxis when necessary and (4) routine Hib immunization of the community.

Chemoprophylaxis

Rifampicin eradicates Hib from the pharynx in approximately 95% of carriers and decreases the risk of secondary invasive illness in household contacts. The risk of invasive disease is increased among unimmunized household contacts younger than 4 years of age; secondary disease in child care contacts is rare when contacts are older than 2 years of age. Treatment of index case with ceftriaxone or cefotaxime eradicates Hib colonization, eliminating the need

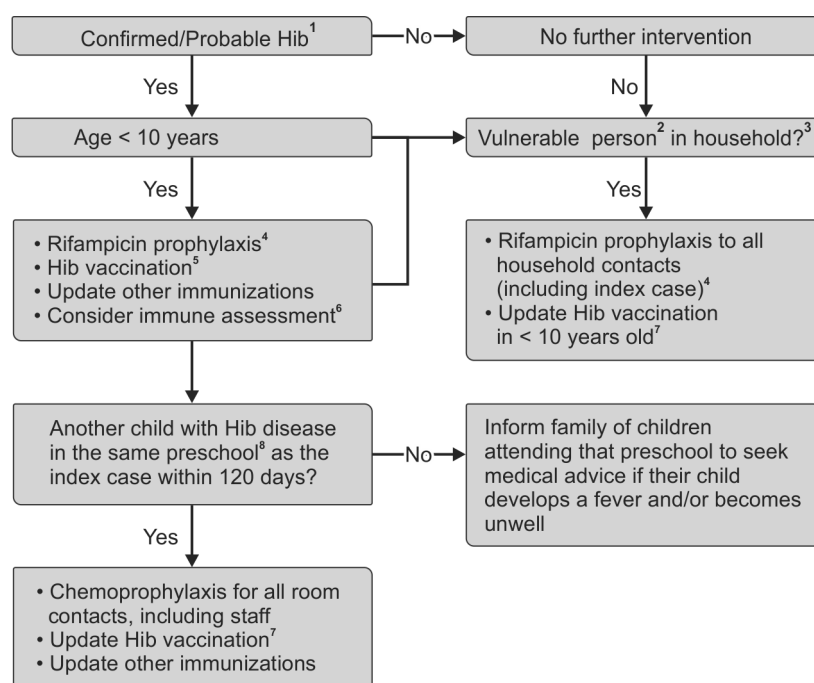

for prophylaxis, whereas those treated with other antimicrobials and who are younger than 2 years of age should receive rifampicin prophylaxis at the end of therapy.

Hib Vaccine

Hib containing vaccines provide 85–95% protection after completion of the schedule. In addition to the effects directly attributed to the vaccine, they reduce nasopharyngeal colonization and carriage of the organism, leading to substantially greater reduction in disease transmission and incidence than can be directly attributed to the effects of the vaccine. This indirect effect or *herd immunity* and reductions in antibiotic resistance by preventing disease and appropriate use of antibiotics have been demonstrated in several postintroduction effectiveness studies. All Hib vaccines are conjugated vaccines where the Hib capsular polysaccharide (polyribosylribitol phosphate or PRP) is conjugated with a protein carrier so as to provide protection in the early years of life when it is most needed. The vaccination schedule for Hib consists of three doses when initiated below 6 months, 2 doses between 6 and 12 months and 1 dose between 12 and 15 months, with a booster at 18 months. For children aged more than 15 months, a single dose may suffice. The interval between two doses should be at least 4 weeks. Immunization can be commenced as early as 6 weeks of age. Details on Hib vaccine are given in Section 23 on immunization.

More than 170 countries now include Hib vaccine in their national immunization program. By contrast, introduction of the vaccine in India has been delayed. In 2008, India's National Technical Advisory Group on immunization recommended inclusion of Hib vaccine into the universal immunization program (UIP). Based on this recommendation, the Government of India recently decided to introduce Hib-containing pentavalent vaccine into the UIP of 10 Indian states.

Flow chart 1 Guidelines for the management of close contacts of Hib. Open access document from: Revised recommendations for the prevention of secondary *Haemophilus influenzae* type b (Hib) disease (Updated 1 July, 2013) by Department of health and Public health England—NHS England. Available from: https://www.gov.uk/government/uploads/system/uploads/attachment_data/file/231009/Revised_recommendations_for_the_preventions_of_secondary_Haemophilus_influenzae_type_b_disease.pdf. Accessed April 16, 2014.

EMERGING TRENDS

The spectacular progress in developed countries in preventing Hib infections by universal vaccination over the past 2 decades has resulted in changes in colonization and epidemiology of invasive *H. influenzae* disease. There has been an observed shift from predominantly serotype b strains to predominantly nontypeable strains. There is no convincing evidence of an increased incidence of invasive disease by nonserotype b strains of *H. influenzae*, i.e., no strain replacement. However, this issue requires continued vigilant surveillance.

IN A NUTSHELL

1. Globally, every year, Hib kills more than 370,000 children under 5 years of age. Nearly 20% of these children are from India.
2. The most common manifestations of invasive *Haemophilus influenzae* disease are bacteremia, meningitis, invasive pneumonia, epiglottitis, cellulitis, infectious arthritis, and osteomyelitis or septic arthritis. Less common infections include endocarditis, endophthalmitis, peritonitis and gangrene.
3. The disease occurs primarily in children aged less than 2 years, particularly in infants. Children between the ages of 4–18 months of age are most at risk.
4. Hib spreads either by direct person to person contact or through respiratory droplets.
5. Dexamethasone is beneficial in diminishing the risk of hearing loss if given before or concurrently with the first dose of antimicrobials.
6. Rifampicin eradicates Hib from the pharynx in approximately 95% of carriers and decreases the risk of secondary invasive illness in household contacts.
7. Hib vaccine can prevent over one-third of pneumonia cases and 90% of Hib meningitis cases.

Chapter 29.9

Pneumococcal Infections

Meenu Singh, Nishant Jaiswal

Pneumococcal disease is the term used to describe infections caused by the bacterium *Streptococcus pneumoniae* (also called *pneumococcus*). Pasteur first isolated the bacterium in 1881 from the saliva of a patient with rabies. Friedlander and Talamon first described the association between the *Pneumococcus* bacterium and lobar pneumonia in 1883, but pneumococcal pneumonia was confused with other types of pneumonia until the discovery of the Gram stain in 1884. By 1940, more than 80 serotypes were known. Efforts to develop effective pneumococcal vaccines began as early as 1911. However, with the advent of penicillin in the 1940s, interest in the vaccine declined, until it was observed that many patients still died despite antibiotic treatment. By the late 1960s, efforts were again being made to develop a polyvalent pneumococcal vaccine. The first pneumococcal vaccine was licensed in the United States in 1977. The first conjugate pneumococcal vaccine was licensed in 2000.

MORPHOLOGY AND VIRULENCE

S. pneumoniae are lancet-shaped, gram-positive, catalase-negative facultative anaerobic organisms. They are typically observed in pairs (diplococci) but may also occur singularly or in short chains. *S. pneumoniae* may or may not be capsulated. Encapsulated strains are pathogenic for humans and other animals, whereas the uncapsulated forms are nonpathogenic. The capsule is the most important virulence factor. Over 90 different capsular serotypes have been characterized.

S. pneumoniae belong to the α -hemolytic group that characteristically produces a greenish color on blood agar because of the reduction of iron in hemoglobin. The bacteria are fastidious and grow best in 5% CO₂ but require a source of catalase (e.g., blood) for growth on agar plates, where they develop mucoid (smooth/shiny) colonies. Pneumococci without a capsule produce colonies with a rough surface. Unlike that of other hemolytic streptococci, their growth is inhibited in the presence of optochin (ethyl hydrocuprein hydrochloride), and they are bile soluble.

Most *S. pneumoniae* serotypes have been shown to cause serious disease, but only a few serotypes produce the majority of pneumococcal infections. The ranking and serotype prevalence differ by patient age group and geographic area. Some serotypes of the *Pneumococcus* may be carried in the nasopharynx without symptoms, with disease occurring in a small proportion of infected individuals. Other serotypes are rarely identified in the nasopharynx but are associated with invasive disease. The incubation period for pneumococcal disease is not clearly defined but it may be as short as one to three days. The organism may spread locally into the sinuses or middle ear cavity, causing sinusitis or otitis media. It may also affect the lungs to cause pneumonia, or cause systemic (invasive) infections including bacteremia and meningitis.

PATHOGENESIS

Pneumococci colonize the human nasopharynx from an early age. Colonization acquisition events are generally described as asymptomatic, but evidence exists to associate acquisition with mild respiratory symptoms, especially in the very young. From the nasopharynx, the bacteria spread either via the bloodstream to distant sites (e.g., brain, joint, bones, peritoneal cavity) or locally to mucosal surfaces where they can cause otitis media or pneumonia. Direct spread from the nasopharynx to the central nervous system

(CNS) can occur in rare cases of skull base fracture, although most cases of pneumococcal meningitis are secondary to hematogenous spread. Pneumococci can cause disease in almost any organ or part of the body; however, otitis media, pneumonia, bacteremia and meningitis are most common.

Pneumococcal diseases occur throughout the world and infect both extremes of life (children under 5 years and elderly). It also affects those with an absent or nonfunctioning spleen and those with other causes of impaired immunity. *Pneumococcus* can cause meningitis and severe pneumonia, leading to an estimated 14.5 million cases of serious illness and 735,000 deaths each year in HIV-negative children under 5 years of age. National estimates of deaths due to *Pneumococcus* among children under 5 years of age ranged from 141,000 in India to fewer than 10 deaths in 46 countries. Nineteen percent of all pneumococcal deaths below 5 years of age occurred in India. Six countries (India, Nigeria, Ethiopia, DR Congo, Afghanistan and China) accounted for more than half of all pneumococcal deaths under age five in 2000.

TRANSMISSION

Pneumococcus resides in the nasopharynx of the asymptomatic human carriers and has no animal or insect vector. It spreads via direct person-to-person contact by respiratory droplet or autoinoculation. Overcrowding, seasonal variation, unhygienic conditions and presence of upper respiratory tract infection or other noninvasive pneumococcal diseases facilitate the spread.

Risk Factors

Lack of exclusive breastfeeding, nutritional deficiencies and indoor air pollution are risk factors for pneumonia, including pneumococcal pneumonia in infants and young children. Asplenic children (both functional and anatomical) particularly with sickle cell disease and immunocompromised children (particularly with HIV infection) are even at a higher risk for invasive disease. Moreover, children living in overcrowded, unhygienic areas and those attending childcare centers have shown more predispositions for invasive pneumococcal disease.

CLINICAL FEATURES

S. pneumoniae causes conjunctivitis, otitis media, sinusitis and pneumonia by direct invasion from the nasopharynx as well as meningitis and bacteremia by invasion and hematogenous spread.

Conjunctivitis

S. pneumoniae is the second most common cause of bacterial conjunctivitis in children; it is a more common cause of epidemic outbreaks among young adults. Acute bacterial conjunctivitis presents typically with burning, irritation, tearing and purulent or mucopurulent discharge. Conjunctival swelling and mild edema of the eyelid may occur as well.

Otitis Media

The most common bacterial pathogen causing otitis media in children and adults is *S. pneumoniae*. It commonly occurs after a viral infection that leads to eustachian tube congestion. It usually presents with a rapid onset of signs and symptoms such as otalgia, irritability in an infant or toddler, otorrhea and/or fever. Complications of acute otitis media include mild conductive hearing loss, vestibular balance dysfunction, tympanic membrane perforation, mastoiditis, petrositis and labyrinthitis. Rarely, intracranial complications may occur, which include meningitis, epidural abscess, brain abscess, lateral venous sinus thrombosis, cavernous sinus thrombosis, subdural empyema and carotid artery thrombosis.

Sinusitis

S. pneumoniae commonly affects the maxillary and the ethmoid sinuses. It is usually preceded by a viral infection, leading to mucosal swelling of the sinuses and obstruction of the ostia. This leads to the development of a purulent discharge and cough. Postnasal drip resulting in malodorous breath and worsening cough during night may also occur. Infection may extend into the cranium, leading to cavernous sinus thrombosis; brain, epidural or subdural abscesses or meningitis.

Pneumonia

Pneumococcal pneumonia is one of the most frequent serious bacterial infections. It may manifest as lobar pneumonia or, less commonly, as bronchopneumonia. It is also a common cause of bacterial community acquired pneumonia in HIV-infected patients. The incubation period of pneumococcal pneumonia lasts only about 1–3 days. Symptoms include an abrupt onset of fever with chills or rigors, pleuritic chest pain, productive cough with mucopurulent and rusty sputum, dyspnea, tachypnea, hypoxia, tachycardia, malaise, weakness and fatigue. Nausea, vomiting and headaches occur less frequently. Complications of pneumococcal pneumonia include pleural effusion, empyema, pericarditis and respiratory failure.

Meningitis

Pneumococcus causes acute purulent meningitis that may be secondary to bacteremia from other foci like pneumonia, direct extension from the infection of the ear, mastoid process or paranasal sinuses, or basilar fracture of the skull or cribriform plate [leading to cerebrospinal fluid (CSF) leakage]. This provides the bacteria residing in paranasal sinuses, nasopharynx or middle ear with access to the CNS.

The presenting signs and symptoms may be nonspecific that include fever, irritability, vomiting, lethargy, anorexia and malaise. Neurologic signs and symptoms include mental status changes, delirium, lethargy, nuchal rigidity, seizures, cranial nerve palsies and other focal neurological deficits. Infants may have a bulging fontanel and poor feeding, whereas elderly patients present with more indolent signs, such as increasing lethargy, nonresponsiveness or coma. Complications of pneumococcal meningitis include hearing loss, seizures, learning disabilities, mental dysfunction and cranial nerve palsies.

Bacteremia

The most common manifestation of invasive pneumococcal disease is bacteremia. It can occur in both immunocompetent and immunosuppressed patients with particular risk in patients who have undergone a splenectomy. Children less than 2 years of age are the most affected. Generally, the presentation is nonspecific. In most patients, high-grade fever develops within 24 hours of positive culture findings, and there is presence of a peripheral WBC count greater than 15,000 cells/ μ L. Complications include meningitis, osteomyelitis, pneumonia, endocarditis, soft tissue and joint infections, and sepsis.

DIAGNOSIS

The laboratory diagnosis in suspected pneumococcal infection includes Gram stain and culture of blood, CSF, sputum, pleural fluid or lung aspirate, joint fluid, bone or other tissue specimens. *Pneumococcus* typically appears as lancet-shaped diplococci on Gram stain. The characteristic capsule can be detected using the Quellung test or by staining using methylene blue. Culture confirms identification and antimicrobial susceptibility testing is

also performed routinely. For epidemiologic purposes, serotyping and genotyping of isolates may also be performed.

TREATMENT

The initial empiric antibiotic therapy pending antibiotic susceptibility tests is determined by local resistance patterns. Penicillin is the drug of first choice. Penicillin and its derivatives can be used for treating susceptible pneumococcal infections. The mechanism of action of penicillins is by inhibition of cell wall synthesis. These can be administered orally or parenterally. The usual doses of penicillin provide adequate serum and body fluid concentrations for susceptible organisms. The coverage of first-generation cephalosporins is similar to penicillin-susceptible strains. Macrolides usually are active against penicillin-susceptible strains of *S. pneumoniae*. Their CSF penetration is poor and, thus, should not be used to treat meningitis. Vancomycin, a glycopeptide antibiotic is the drug of choice (along with third-generation cephalosporins) against pneumococcal meningitis.

Carbapenems are also effective broad-spectrum antibiotics but should be reserved for specific cases due to potential for development of resistance to multiple organisms. β -lactams or macrolides are generally preferred but treatment has become more challenging as resistant strains have emerged worldwide. The rapid development and spread of antibiotic resistance has occurred due to multiple factors, of which prior antibiotic use, young age and day-care attendance are the predominant risk factors.

The method of resistance of pneumococci varies greatly for different antibiotics. Resistance to penicillins is mediated by alterations in the cell wall penicillin-binding proteins, cephalosporins, sulfonamides, trimethoprim-sulfamethoxazole by amino acid changes, macrolides by methylation or efflux pump, quinolones by decreased permeability, efflux pumps, and alteration of enzymes and chloramphenicol by inactivating enzymes. Resistance to multiple antibiotics is obtained by a bacterium by a transposon or is encoded in a cassette containing genetic information.

Due to increasing resistance of pneumococcal isolates to trimethoprim-sulfamethoxazole, it is not preferred unless drug susceptibilities are known and use of beta-lactams is contraindicated.

Specific Therapy

The first-line treatment for *acute otitis media* and *sinusitis* is amoxicillin 80–90 mg/kg/day. If no improvement is observed within 48–72 hours, patients should be re-evaluated and switched to amoxicillin-clavulanate or a second- or third-generation oral cephalosporin. If the pneumococci are highly resistant, they may require treatment with parenteral ceftriaxone to achieve adequate serum levels of antibiotics.

For mild-to-moderate bacterial *community acquired pneumonia*, the first-line therapy is amoxicillin (90 mg/kg/day in two doses or 45 mg/kg/day in three doses) for previously healthy infants, preschool and school-aged children, and adolescents. In children older than 5 years, macrolides are added for coverage of atypical organisms. In hospitalized previously healthy children and adolescents, ampicillin or penicillin G is the recommended first-line treatment. In critically ill or immunocompromised children, empiric therapy should include vancomycin and a broad-spectrum cephalosporin until antibiotic susceptibilities are available.

The empiric therapy for meningitis consists of vancomycin and cefotaxime or ceftriaxone at meningeal doses. Antibiotics should be changed accordingly when antibiotic susceptibility test results are available.

PREVENTION

Vaccines

Two vaccines are available against *S. pneumoniae*: a pneumococcal conjugate vaccine (PCV13/PCV10) and a polyvalent polysaccharide vaccine (PPV23). Conjugated vaccine is recommended for all children aged 6 weeks to 59 months. The schedule varies according to age and underlying medical conditions. Children who begin vaccination at age less than or equal to 6 months, three-dose primary series is given beginning at about 2 months at every 2-month interval, followed by a fourth dose at age 12–15 months of age. For children who begin vaccination at 7–11 months of age, a two-dose primary series and a booster are given. From age 12 to 23 months, only 2 doses are given. From 24 months to 9 years of age, children are given only one dose of the vaccine. Adults, who are immunocompromised, have functional or anatomic asplenia, CSF leaks or cochlear implants and are not previously vaccinated with PPV23 should receive a dose of PCV13 first, followed by a dose of PPV23 at least after 8 weeks.

Polysaccharide vaccine is ineffective in children less than 2 years of age but causes reduction by 50% for invasive pneumococcal infection and bacteremia. It provides protection lasting for many years, but one-time revaccination is recommended after more than or equal to 5 years for patients with functional or anatomic asplenia and immunocompromised patients. It is usually indicated for adults more than or equal to 65 years and before splenectomy. It is not recommended for children less than 2 years or in those who are hypersensitive to the vaccine's components.

Prophylactic Antibiotics

Prophylactic penicillin V 125 mg per oral twice a day is recommended for children with functional or anatomic asplenia who are less than 5 years of age. The duration for chemoprophylaxis is variable, but it is usually continued throughout childhood and into adulthood for high-risk patients with asplenia. Penicillin 250 mg per oral twice a day is recommended for older children or adolescents for at least 1 year after splenectomy.

IN A NUTSHELL

1. *Pneumococcus* is gram-positive lancet-shaped catalase-negative facultative anaerobic diplococci. Encapsulated forms are virulent and over 90 serotypes are known based on the capsule.
2. *Pneumococcus* resides in the nasopharynx of the asymptomatic human carriers and has no animal or insect vector and spreads via direct person-to-person contact by droplet spread or direct inoculation.
3. *Pneumococcus* causes both invasive and noninvasive diseases, like otitis media, community acquired pneumonia and meningitis, etc.
4. Amoxicillin is the drug of choice for otitis media and community acquired pneumonia, and vancomycin along with cefotaxime are the drug of choice for pneumococcal meningitis.
5. Pneumococcal conjugate vaccines are used to immunize children less than 2 years of age against *pneumococcus*. Pneumococcal polysaccharide vaccine is recommended for elderly, before splenectomy and a revaccination with PPSV is indicated for patients more than 5 years of age with functional or anatomical asplenia.

Chapter 29.10

Streptococcal Infections

Pramod Sharma

Streptococcus is a large group of nonmotile, nonspore forming, catalase and oxidase negative, spherical gram-positive cocci arranged in chains. They are part of the normal flora of humans and animals. Some of them are human pathogens and may be responsible for a wide range of invasive and noninvasive infections. The name is derived from the Greek word *streptos* meaning twisted chains; under a microscope, they resemble a string of small pearls.

CLASSIFICATION

Streptococci are divided into obligate anaerobes and facultative organisms. The former are designated peptostreptococci and are beyond the scope of this chapter. The aerobic and facultative anaerobes are classified based on their hemolytic properties. Brown (1919) categorized them into three varieties based on their growth in horse blood agar culture plates.

1. *Alpha-hemolytic Streptococci* cause partial hemolysis and a greenish discoloration. Hence, they are called *Streptococcus viridians* (viridians-green). These are normal commensals but may cause opportunistic infections at times.
2. *Beta-hemolytic Streptococci* Most pathogenic Streptococci belong to this group.
3. *Gamma streptococci* Include the fecal Streptococci (*Streptococcus faecalis*) or enterococci.

Lancefield Grouping

Hemolytic Streptococci were classified serologically into groups based on nature of a carbohydrate (C) antigen on the cell wall. Majority of organisms producing human infections belong to Group A. Group A β -hemolytic streptococci (GAS) are known as *Streptococcus pyogenes*. Lancefield grouping of other hemolytic Streptococci is shown in **Table 1**. GAS are further divided into types based on the protein antigens (M, T and R) present on the cell surface (*Griffith typing*). More than 20 types of GAS have been identified on the basis of M protein (located on cell surface and fimbriae) antigen typing. M protein sequence typing, using polymerase chain reaction is based on sequencing the *emm* gene, encoding the M protein. Chromosomal arrangements of *emm* subfamily genes reveal 5 major patterns of *emm*: Pattern A to E.

GROUP A STREPTOCOCCAL INFECTIONS

S. pyogenes It causes suppurative infections chiefly of upper respiratory tract (pharyngitis) and skin, viz., impetigo and pyoderma. GAS also causes scarlet fever, erysipelas, necrotizing fasciitis, and toxic shock syndrome (TSS). It is less commonly implicated in cellulitis, vaginitis, pneumonia, endocarditis,

pericarditis, osteomyelitis, omphalitis and suppurative arthritis. GAS triggers two nonsuppurative postinfectious complications: acute glomerulonephritis and acute rheumatic fever (ARF).

Epidemiology

Streptococcal pharyngitis is highly communicable and usually results from contact with respiratory tract secretions of an infected person. It affects all age groups but is more common in school-aged group (5–15 years). The disease is more common during winter, late autumn and spring season and in temperate climates. Communicability is highest during acute infection and from untreated persons. Patients are not contagious within 24 hours of initiation of appropriate antibiotics.

Impetigo (pyoderma) is more common in tropical climates and warm seasons and spreads by direct contact. GAS invades open skin lesions, viz., insect bites, burns, traumatic wounds, etc. Infections of surgical wounds and puerperal sepsis are usually transmitted by hands, anal and vaginal carriers. Neonatal infections can result from intrapartum or contact transmission which present as cellulitis, omphalitis or necrotizing fasciitis.

Invasive GAS infections occur mostly in infants and older age group. Varicella has been identified as the most common risk factor. Other risk factors include HIV infection, intravenous drug use, diabetes mellitus and chronic cardiac and pulmonary disease. The entry site is believed to be skin or mucous membrane though in 50% cases, the portal of entry is not known.

Pathogenesis

The major surface protein of GAS is M protein. The presence of M protein on a GAS isolate correlates with its capacity to resist phagocytic killing and improves adherence. This resistance is overcome by M protein-specific antibodies. GAS elaborates other antigens and enzymes responsible for virulence of different subtypes. The polysaccharide capsule protects from lysozymal defense of hosts. Streptokinase digests clots, hyaluronidase digests binding substance in connective tissues, DNases digest DNA, streptolysins S and O cause hemolysis and damage cell membranes and tissues, pyrogenic toxin—key toxin for rash of scarlet fever, affects temperature regulating center and C5a protease hinders complement and neutrophilic response.

Clinical Manifestations

Incubation period is 2–5 days for pharyngitis, and 7–10 days for impetigo.

Pharyngitis

Acute pharyngotonsillitis is the most common GAS infection and symptoms include sore throat, fever with chills, malaise and abdominal discomfort and vomiting. Exudative pharyngitis is commonly accompanied by enlarged, tender anterior cervical lymph nodes, fever and purulent exudates over the posterior pharyngeal wall (*Centor criteria*). Serous rhinitis, moderate fever, irritability, anorexia and lymphadenopathy may be seen

Table 1 Lancefield grouping of other hemolytic Streptococci

Species	Hemolytic group	Lancefield group	Diseases
<i>Streptococcus agalactiae</i> (GBS)	Beta	B	Neonatal meningitis, septicemia
Enterococci (<i>S. faecalis</i>)	Gamma	D	Endocarditis, UTI, rarely suppurative infections
<i>S. bovis</i> (Nonenterococci)	Gamma	D	Endocarditis, bacteremia
Viridans (<i>S. sanguis</i>)	Alpha	—	Endocarditis, dental caries (<i>S. mutans</i>), brain abscess

in toddlers. Classic Streptococcal pharyngitis is rare in children younger than 3 years.

Impetigo

Skin is the second most common site of GAS infection. The usual sites of involvement are face (around nose and mouth) and legs. Lesions start as red papules which quickly evolve into painless vesicular and pustular lesions that break down and coalesce to form honeycomb-like crusts.

Scarlet Fever

Uncommon in Indian population, it is characterized by confluent erythematous, finely papular sandpaper-like rash which blanches on pressure. It is caused by pyrogenic exotoxin. Rash appears within 24–48 hours of symptoms. It begins around neck and spreads to trunk and extremities with circumoral pallor. Tongue is usually coated and has swollen papillae which on desquamation becomes reddened and gives a *strawberry* appearance.

Necrotizing Fasciitis

This is also called Streptococcal gangrene. It is an acute rapidly progressive, severe deep-seated infection of the subcutaneous tissue associated with extensive destruction of the superficial and deep fascia. It may arise following minor trauma or from hematogenous spread of GAS from the throat to the site of a blunt trauma or muscular strain.

Invasive Group A β -hemolytic Streptococci Infections

Invasive GAS infections can be associated with *Streptococcal* TSS. Ability of certain Streptococcal pyogenic exotoxins to function as superantigen leads to a triggered hyperimmune response. This severe disease is characterized by shock, multiple organ dysfunction syndrome (MODS) and hematological and neurological anomalies.

Group A β -hemolytic Streptococci infections are seldom associated with sudden onset of obsessive compulsive disorder or tic disorder, which has been described as pediatric autoimmune neuropsychiatric disorders associated with *S. pyogenes* (PANDAS).

DIAGNOSIS

Laboratory confirmation of GAS infection is confirmed by culture on sheep blood agar. Differentiation of group A from other beta-hemolytic Streptococci is done by latex agglutination, coagglutination, fluorescent antibody or precipitation techniques performed on the grown colonies. An adequate specimen is taken by vigorous swabbing of both tonsils and posterior pharynx. A single culture has a sensitivity of 90–95% for detecting the presence of GAS in the pharynx. Other rapid diagnostic tests are mostly based on nitrous acid extraction of group A carbohydrate antigen from cultured organisms. These rapid diagnostic tests are >95% specific. Commercially available slide agglutination (streptozyme) test detects antibodies to several Streptococcal antigens. Discs containing 0.04 U of bacitracin inhibits the growth of > 95% of group A strains while 80–90% of nongroup A are resistant to this antibiotic.

TREATMENT

Pharyngitis

Penicillin V is the drug of choice of GAS pharyngitis. In children allergic to penicillin, erythromycin, clarithromycin or azithromycin is used. Amoxicillin is a good alternative and can be given once daily in a dose of 50 mg/kg for 10 days. A 10-day course of a narrow spectrum oral cephalosporin is recommended for most penicillin allergic children.

Impetigo

Local application of mupirocin ointment helps preventing person-to-person spread and eradicating localized disease. Systemic antimicrobials are indicated in multiple lesions and impetigo in family.

Parenteral antimicrobials are required in severe infections (meningitis, sepsis, pneumonia, endocarditis, septic arthritis, necrotizing fasciitis, osteomyelitis, surgical wound infection, neonatal omphalitis and Streptococcal shock syndrome). The treatment of various Streptococcal infections is shown in **Table 2**.

Table 2 Treatment of Streptococcal infection

Infection	Treatment
Pharyngitis	Penicillin V 250 mg PO tid or 500 mg PO bid \times 10 days Or erythromycin, oral cephalosporin, azithromycin Benzathine penicillin G (children <27 kg—600,000 IU IM, children >27 kg—1,200,000 IU IM \times 10 days)
Impetigo	Same as pharyngitis
Erysipelas/cellulitis	Severe: Penicillin G 1–2 mU IV q4h Mild to moderate: Procaine penicillin 1–2 mU IM bid
Necrotizing fasciitis/myositis	Surgical debridement; plus penicillin G 2–4 mU IV q4h; plus clindamycin 600–900 mg q8h
Pneumonia/empyema	Penicillin G 2–4 mU IV q4h; plus drainage of empyema
Streptococcal toxic shock syndrome	Penicillin G 2–4 mU IV q4h; plus clindamycin 600–900 mg q8h; plus intravenous immunoglobulin, 2 g/kg single dose

NONSUPPURATIVE SEQUELAE OF STREPTOCOCCAL INFECTIONS

Poststreptococcal Acute Glomerulonephritis

Glomerulonephritis can follow GAS infection of either the pharynx or the skin and depends on the prevalence of nephritogenic strain of GAS in the community. M serotype 12 is most frequently associated with poststreptococcal acute glomerulonephritis after pharyngitis and M type 49 is the serotype most commonly related to pyoderma-associated nephritis. Other strains implicated are M types 4 and 25. In most cases, there is a history of sore throat or pyoderma, latent period being 7–14 days in former and 2–4 weeks in later. The pathogenesis appears to be immune-mediated. Immunoglobulins, complement components and antigens that react with Streptococci are present in the glomeruli early in the course of the disease and antibodies elicited by nephritogenic Streptococci react with renal tissues to propagate glomerular injury. Immune complexes may be in circulation or formed in situ. Diagnosis is based on an evidence of recent Streptococcal infection: Antistreptolysin O (ASO) titers are raised in blood and C3 levels and CH 50 levels are decreased. Clinical course and management issues are discussed in Section 41 on kidney diseases.

Acute Rheumatic Fever

Acute rheumatic fever is delayed nonsuppurative sequelae of acute tonsillopharyngitis caused by GAS. There is usually a latent period of 2–3 weeks between pharyngitis and rheumatic fever. Not all serotypes of group A *Streptococcus* are associated with rheumatic fever. There are certain serotypes (M type 1, 3, 5, 6, 18, 24) which are commonly isolated from patients of rheumatic fever. Streptococcal

antigenic components (M protein, cell membrane, cell wall group A carbohydrate, capsular hyaluronate) mimic normal human tissue antigens (heart, brain, joint) leading to abnormal humoral and cellular immune responses (*molecular mimicry*). Rheumatic valves display increased expression of vascular cell adhesion molecule 1 (VCAM-1) a protein that mediates the adhesion of lymphocytes. Rate of development of rheumatic fever in children with untreated Streptococcal infection is estimated to be 3%. Incidence of recurrence with a subsequent untreated infection is about 50%.

Another theory is cytotoxic theory according to which rheumatic fever is caused by several cytotoxic enzymes produced by group A *Streptococcus*, but this theory fails to explain latent period between pharyngitis and rheumatic fever. Upcoming evidence supports the role of host susceptibility and genetic predisposition in rheumatic fever and components of MHC Class II—the DR 7 allele on chromosome 6 is associated with *RHD*. Detailed description of ARF follows in Section 40 on cardiovascular diseases.

Supporting evidence of recent Streptococcal infection is essential for the diagnosis of rheumatic fever. Only 10–20% of throat culture or rapid Streptococcal antigen tests are positive. Evidence of recent infection is thus based on elevated or rising serum antistreptococcal antibody titer. Raised ASO is seen in 80–85% cases and 95–100% patients of ARF can be diagnosed if three different antibody titers are measured (*ASO*, *anti-DNase B* and *hyaluronidase*).

GROUP B STREPTOCOCCAL INFECTIONS

Group B streptococci (GBS) or *S. agalactiae* are gram-positive diplococci which are classified into nine serotypes on the basis of capsular polysaccharides. Serotype III is the most common pathogen for early onset meningitis and most late onset infections in infants. GBS commonly colonize gastrointestinal and genitourinary tracts. Maximum colonizing rate (15–40%) is observed in pregnant women and newborn infants. GBS can be acquired in nursery from hospital personnel by hand contamination. The risk of early onset neonatal infection (0–6 days) increases with prematurity, prolonged rupture of membranes (> 18 hours), chorioamnionitis, GBS bacteriuria during pregnancy, intrapartum fever more than or equal to 38°C ($\geq 100.4^{\circ}\text{F}$) or previous infant with invasive GBS disease. Late onset disease (7 days–3 months) manifests as occult bacteremia or meningitis.

Other focal infections are osteomyelitis, adenitis, septic arthritis and cellulitis. Ampicillin plus an aminoglycoside (gentamicin) are initial treatment of choice. Infants with bacteremia or soft tissue infection should receive penicillin in a dosage of 200,000 U/kg/day in divided doses and in cases of meningitis should receive 400,000 U/kg/day. In meningitis, 14-day course should be given to prevent relapses.

IN A NUTSHELL

1. Streptococci are classified as alpha-hemolytic (*S. viridans*), beta-hemolytic (Group A: *S. pyogenes*; Group B: *S. agalactiae*) and gamma-hemolytic (*S. fecalis*).
2. *S. pyogenes* causes pharyngitis, impetigo and pyoderma. GAS also cause scarlet fever, erysipelas, necrotizing fasciitis, and TSS. They are also implicated in cellulitis, vaginitis, pneumonia, endocarditis, pericarditis, osteomyelitis, omphalitis and suppurative arthritis. GAS triggers two nonsuppurative postinfectious complications: acute glomerulonephritis and ARF.
3. Group B streptococci or *S. agalactiae* commonly colonize gastrointestinal and genitourinary tracts. These result in early onset sepsis and meningitis in newborn infants in the western world. These organisms are less common in Indian settings.

Chapter 29.11

Staphylococcal Infections

Zaki Syed

Staphylococci are ubiquitous in nature and can survive as both commensals and pathogens. They are aerobic or facultative anaerobic, nonmotile, nonsporulating, gram-positive cocci that grow in pairs and clusters which resemble grapes (*staphylo* in Greek means *bunch of grapes*). They belong to the family *Staphylococcaceae* and can survive for long on environmental surfaces in varying conditions. They are catalase-positive unlike streptococcal species. The genus *Staphylococcus* consists of more than 30 distinct species. **Flow chart 1** shows the classification of the clinically important species depending on the biochemical tests.

Two species are commonly associated with Staphylococcal disease in humans: *S. aureus* and *S. epidermidis*. *S. aureus* causes infections ranging from trivial skin infection to lethal invasive disease. In comparison, *S. epidermidis* is less virulent and invasive except in an immunocompromised host or in the presence of an indwelling foreign body (e.g., catheter).

EPIDEMIOLOGY

Staphylococci cause millions of community-acquired and health-care associated infections in the developing world each year. About 50–60% of these infections are caused by methicillin-resistant *S. aureus* (MRSA). MRSA has now become endemic in India with incidence varying from 25% to 50%. Before mid-1990s, MRSA strains were exclusively hospital-associated, but recently their prevalence has increased in the community too. The community-acquired MRSA strains have the ability to cause serious infections even in immunocompetent individuals which is a cause for concern.

About 50% of healthy individuals may be persistently or temporarily colonized with *Staphylococci* in sites like the nose, skin, hairs, nails, axillae and perineum. The rate of colonization is comparatively much higher in immunosuppressed individuals. Asymptomatic carriers are at increased risk of infection for themselves and others. Other routes of transmission include: contact with infected persons, airborne spread and contact with contaminated objects. *Staphylococci* are widespread in the environment and can be cultured from virtually all known surfaces. Airborne transmission can occur in health facilities having operating rooms with poor ventilation. *S. aureus* is a common cause for nosocomial infections. Transient colonization of the hands of hospital personnel can result in transmission of infection amongst patients. This can be minimized by effective handwashing. In addition, hospital personnel with mild or inapparent lesions, such as stye, furuncle or paronychia should be adequately treated to limit spread. *Coagulase-negative staphylococci* (CoNS) commonly inhabit skin and mucus membrane of normal humans. The widespread use of invasive therapeutic modalities (e.g., mechanical ventilation, central venous catheters) has increased the incidence of infection from CoNS.

PATHOGENESIS

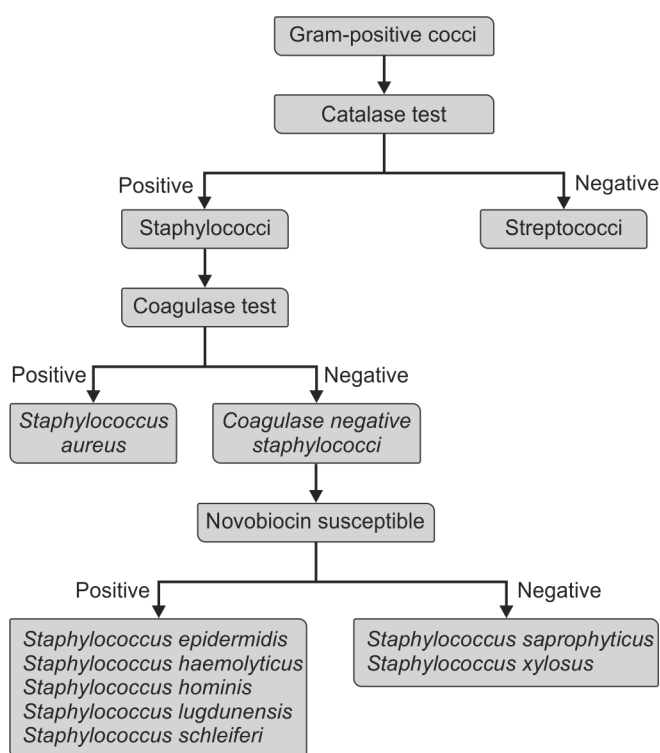

Virulence Factors

Staphylococci can colonize the skin, invade blood stream, evade host immunological responses, form protective biofilms and develop resistance to several antibiotics. The virulence factors of *Staphylococci* are shown in **Box 1**. They have the ability to produce a biofilm, or slime layer around itself. This biofilm enhances the adhesion of the organism to foreign surfaces, resists phagocytosis by macrophages and decreases the penetration of antimicrobial agents. **Table 1** compares the virulence factors of *S. aureus* and *S. epidermidis*.

Mechanism of Disease

Staphylococci cause disease by two mechanisms: tissue invasion and toxin-mediated. The host defense consists of an intact skin barrier and innate immune system. Conditions where the skin barrier is breached (e.g., burns, chronic skin disease, skin abrasions, and surgical procedures), increases the risk of Staphylococcal infections. The second defense is the host's innate immune system wherein the *Staphylococci* are killed by the neutrophils at the infection site. However, *Staphylococci* produce various virulence factors that can block each step of this host response. The presence of large numbers of organisms can overwhelm the host innate-immune response resulting in the spread of infection. Congenital/acquired neutrophil disorders (e.g., Jobs syndrome) increase the risk of Staphylococcal infection. *S. saprophyticus* can adhere to uroepithelial cells and result in urinary tract infection in patients with urinary catheters in situ. Toxin-mediated diseases of *Staphylococci* are: food poisoning, toxic shock syndrome (TSS) and Staphylococcal-scalded skin syndrome. Staphylococcal food poisoning is caused by a preformed heat-stable enterotoxin. TSS is caused by toxic shock syndrome toxin-1 (TSST-1), or other Staphylococcal enterotoxins, which act as superantigens. These bind to major histocompatibility complex class II molecules of antigen presenting cells. This binding stimulates the release of several cytokines from T-cells causing septic shock and death. The exfoliative toxins, A or B, secreted by the *S. aureus* can cause Staphylococcal-scalded skin syndrome. These toxins are proteases that specifically cleave desmoglein 1 (a desmosomal protein) that attaches the superficial epidermis to the underlying stratum granulosum.

Flow chart 1 Classification of clinically important Staphylococcal species

BOX 1 List of various virulence factors of *Staphylococci* with their pathogenetic mechanism*Thwart host defenses*

- Microcapsule
- Protein A
- Coagulase
- Slime layer
- Fatty acid metabolizing enzyme
- Leukocidin

Invade tissue

- Proteases
- Nucleases
- Lipases
- Hyaluronidase
- Staphylokinase

Resistance determinants

- *SCCmec* type IV: Resistance to methicillin
- *SCC₄₇₆*: Resistance to fusidic acid

Elicit sepsis syndrome

- Toxic shock syndrome toxin
- Enterotoxins (A, B, C, G, H, L, and O)
- Cytolytic toxins (a, b, g, and d)
- Exfoliative toxin (A and B)

Pore-forming toxins

- Panton-Valentine leukocidin (PVL) (*LukSPV+LukPFV*): Necrosis, edema
- LukE+LukD: Destruction of intestinal microvilli causes postantibiotic diarrhea
- LukEv+LukDv: Necrosis
- α -hemolysin: Necrosis, vascular leakage, and shock

Attach to endothelial cells and basement membrane

- Binding proteins for fibrinogen, fibronectin, laminin, collagen, vitronectin, and thrombospondin.

Table 1 Comparison of the virulence factors of *Staphylococcal* species

Virulence factor	<i>S. aureus</i>	<i>S. epidermidis</i>
Protein A	+	–
Coagulase	+	–
Catalase	+	+
Hyaluronidase	+	–
Staphylokinase	+	–
Lipase	+	+
Beta-lactamase	+	–

CLINICAL FEATURES***Staphylococcus aureus* Infections**

The symptomatology varies depending upon the site of infection.

Skin and Soft Tissue Infections

S. aureus commonly causes skin and soft tissue infections. These include impetigo, folliculitis, hydradenitis, furuncle, pyomyositis, carbuncle, abscess, erysipelas, cellulitis, necrotizing fasciitis and Staphylococcal scalded skin syndrome. Predisposing factors include: skin diseases, skin damage (e.g., trauma) and poor personal hygiene. *Staphylococcus* can also cause nosocomial skin infections. Community-associated MRSA can cause recurrent skin and soft tissue abscesses.

Bacteremia and Sepsis

Staphylococcal bacteremia and sepsis can be either primary or secondary to any localized infections. Organisms can localize

subsequently at any site, e.g., heart valves, lungs, joints, kidneys and bones. The clinical presentation of *S. aureus* sepsis is similar to sepsis due to other bacteria. Congenital/acquired immunosuppression predisposes to Staphylococcal bacteremia. In Staphylococcal bacteremia, the possibility of endocarditis, osteomyelitis or other metastatic deep infection must be considered.

Bones and Joints

S. aureus can cause acute/chronic osteomyelitis and septic arthritis through hematogenous seeding, trauma or surgical procedure. Long bones are commonly affected. The commonly affected joints are the wrist, hip, knee and ankle joints. Treatment includes antimicrobial therapy and drainage of the infected joint by needle aspiration, arthrotomy, or arthroscopically.

Respiratory Tract

S. aureus can rarely cause upper respiratory tract infections, otitis media, suppurative parotitis and sinusitis. Staphylococcal sinusitis and pneumonia are common in cystic fibrosis. Tracheitis complicating viral croup can develop due to *S. aureus*. Patients present with high fever, leukocytosis, severe obstruction of upper airway, or a shock-like picture. Treatment requires antibiotics and careful airway management. *S. aureus* can cause pneumonia by two ways: primary through hematogenous spread; secondary after a viral infection (e.g., influenza). *S. aureus* can cause necrotizing pneumonitis, interstitial pneumonia, empyema, lung abscess, pneumatocoeles, pyopneumothorax and bronchopleural fistula. *S. aureus* and MRSA in particular can cause hospital-acquired and ventilator-associated pneumonia with a high mortality. The diagnosis is done by examination of Gram stain of tracheal aspirate, sputum or lavage which shows the organism and several neutrophils. The culture is highly sensitive but less specific.

Central Nervous System

Community-acquired meningitis due to *S. aureus* is uncommon. Predisposing factors include: surgical procedures (e.g., shunt insertion, craniotomy), head trauma, endocarditis, epidural or brain abscess, cavernous sinus thrombosis and immunosuppression. Mortality is high ranging from 30% to 50%. The CSF profile of *S. aureus* meningitis is similar to other bacterial causes of meningitis.

Heart

Staphylococcal bacteremia may cause infective endocarditis even on native valves. Perforation of valves, heart failure, conduction disturbance, myocardial abscess, acute hemopericardium, purulent pericarditis and sudden death may occur.

Kidney

S. aureus can occasionally cause renal/perinephric abscess and urinary tract infection by hematogenous spread. Instrumentation of the genitourinary tract can result in ascending infections.

Prosthetic Device-related Infections

S. aureus can cause infection of various prosthetic devices like prosthetic valves, peritoneal/intraventricular catheters, intravascular catheters and vascular grafts. CoNS infections of prosthetic devices have a more indolent presentation as compared to *S. aureus* device-related infections which presents acutely and progresses rapidly with both localized and systemic manifestations. Treatment is antibiotic therapy and removal of the device.

Toxin-mediated Disease

Food poisoning The source can be an infected or colonized food handler. It has a short incubation period and the patient presents

within 2–6 hours with nausea, vomiting, abdominal pain and diarrhea. Fever is absent and the illness is self-limiting. Treatment is entirely supportive.

Toxic shock syndrome The causes of TSS are shown in **Box 2**. The disease starts abruptly with high fever, diarrhea, vomiting, headache and myalgia. A diffuse erythematous macular rash appears within 24 hours. The diagnostic criteria are shown in **Box 3**. Complications include acute respiratory distress syndrome, myocardial dysfunction, and renal failure. Recovery occurs within 7–10 days and is associated with desquamation, particularly of palms and soles. Blood cultures are usually negative. Removal of the source of infection (tampons, nasal packs), parenteral administration of a beta-lactamase resistant antibiotic (nafcillin or a first generation cephalosporin) for methicillin-susceptible, penicillinase-resistant *S. aureus* (MSSA) or vancomycin for MRSA strains along with aggressive supportive treatment is recommended. Clindamycin may be added in severe cases to terminate toxin production. Even with treatment, the overall mortality rate is 3%.

BOX 2 Risk factors of Staphylococcal toxic shock syndrome

- Menstruating women using tampons
- Use of vaginal devices (diaphragm, contraceptive sponge)
- Vaginal—postpartum or following infection
- Surgical wounds like hernia, mastoplasty and arthroscopy
- Respiratory tract infections (sinusitis, tracheitis, pneumonia, empyema)
- Abscesses, burns
- Osteomyelitis
- Varicella infection
- Nasal packing.

BOX 3 Diagnostic criteria of Staphylococcal toxic shock syndrome developed by the Centers for Disease Control and Prevention

Major criteria: All four should be present:

1. **Fever:** Temperature $>38.9^{\circ}\text{C}$
2. **Rash:** Diffuse macular erythroderma on the trunk
3. **Desquamation:** 1–2 weeks after onset, mainly of palms and soles
4. **Hypotension:** Systolic blood pressure <90 mmHg for adults and $<5^{\text{th}}$ centile for age for children <16 years of age or orthostatic syncope

Minor criteria: Three or more should be present:

1. **Gastrointestinal:** Vomiting and/or diarrhea at the onset of illness
2. **Muscular:** Severe myalgia or creatine kinase $>$ twice upper limit of normal
3. **Mucus membrane:** Hyperemia of the vaginal, oropharyngeal or conjunctival mucosa
4. **Renal dysfunction:** Blood urea nitrogen or creatinine level at least twice upper limit of normal, or > 5 white blood cells per high power field in urine in the absence of urinary tract infection
5. **Liver dysfunction:** Total bilirubin, aspartate aminotransferase or alanine transferase at least twice upper limit of normal
6. **Thrombocytopenia:** Platelet count < 1 lac/cumm
7. **Central nervous system:** Altered consciousness without focal neurological signs in the absence of fever and hypotension

Exclusion criteria: Normal results on the following tests (if performed):

1. Negative blood, throat or cerebrospinal fluid cultures (except occasionally for *S. aureus*)
2. Absence of another explanation.

Staphylococcal-scalded skin syndrome The disease commonly affects infants but can occasionally be seen in adults too. The illness varies from localized blister formation to exfoliation of much of the skin surface. The mucus membranes are usually spared. Constitutional symptoms like lethargy, fever, irritability and poor feeding are present in more generalized infection.

Infections with Coagulase Negative *Staphylococcus*

As CoNS are less virulent, they cause clinical disease usually in an immunocompromised host or in the presence of a foreign body in situ. CoNS can cause bacteremia and endocarditis in patients with catheter or shunt in situ. It can also cause shunt and catheter infections. CoNS bacteremia is indolent and usually does not progress to septic shock. Central venous catheter infection presents with fever, leukocytosis, tenderness and erythema at the exit site or along the subcutaneous tunnel. Most shunt infections due to CoNS occur within 2 months of the operation. Clinically, it presents with meningeal signs and peritonitis due to the intra-abdominal position of the distal end of the shunt tubing.

DIAGNOSIS

Staphylococcus aureus

The gold standard for diagnosis of *S. aureus* infection is isolation of the organism in cultures of blood, tissue or pus. Gram stain can provide a provisional diagnosis of Staphylococcal infection. The specificity of isolating *S. aureus* from blood or other sterile body sites is 100%. Isolation of *S. aureus* from culture of a respiratory specimen lacks specificity because of nasopharyngeal colonization in some uninfected individuals. Serologic assays are not useful. Susceptibility testing should be performed to guide antimicrobial therapy. Also, it will determine sensitivity of the isolate to methicillin. Diagnosis of Staphylococcal food poisoning is made on epidemiologic and clinical findings. Culture of the contaminated food should be done and tested for enterotoxin.

Coagulase-negative *Staphylococcus*

S. epidermidis is a common skin inhabitant and can contaminate inappropriately collected blood cultures. Hence, differentiating true bacteremia from contamination becomes difficult. True bacteremia is more likely if: there is rapid growth of blood cultures (within 24 hours); more than or equal to two blood cultures are positive with same CoNS; the peripheral venous blood culture has a quantitative colony count comparable to that drawn from central venous catheter; and clinical symptomatology and laboratory findings compatible with CoNS sepsis are present which resolve after therapy.

MANAGEMENT

Staphylococcus aureus

All suppurative collections should be relieved by incision and drainage. In prosthetic-device infections, the device should be removed. If removal is impossible or the infection is due to CoNS, an initial attempt at medical therapy should be tried. Treatment should be started with an antibiotic depending upon the severity of infection and the Staphylococcal susceptibility pattern of the area. Penicillin or amoxicillin should not be used, as more than 90% of all Staphylococcal isolates are penicillin-resistant. Quinolones are not recommended for use in serious infections due to low cure rates. The indications for antimicrobial therapy are shown in **Box 4**.

Skin and soft tissue infections can be usually managed by oral antibiotics and drainage. Oral dicloxacillin, cephalexin, amoxicillin-clavulanate, trimethoprim-sulfamethoxazole or doxycycline is effective for MSSA. Patients with hypersensitivity to penicillin can be treated with clindamycin for skin, soft tissue, bone and joint infections.

Parenteral treatment should be started in serious infections till the patient has been afebrile for 72 hours and signs of infection have decreased. Then oral therapy is given for at least 3 weeks or longer depending on the clinical response, radiological and laboratory findings. The drugs used for treatment of serious

BOX 4 Indications for antibiotic therapy in Staphylococcal infection

- Infections like cellulitis and pneumonia
- Infection where drainage is impossible or inadequate
- Presence of systemic signs and symptoms
- Invasive disease, i.e., secondary sites of infection, involvement of deep tissues, vital organs and sterile sites
- Bacteremia.

infections are shown in **Table 2**. Rifampin or gentamicin may be added for synergy. After starting the treatment, improvement in the general condition of the patient (e.g., toxicity, feeding and activity) should be monitored.

Vancomycin Resistance

Three types of Staphylococcal resistance to vancomycin have emerged recently:

1. *Vancomycin-intermediate S. aureus* (VISA) [minimum inhibitory concentration (MIC) 4–8 mcg/mL] Reduced

susceptibility in these strains is due to the synthesis of an unusually thickened cell wall containing dipeptides reducing availability of the drug for intracellular target molecules.

2. *Heterogeneous vancomycin-intermediate S. aureus* (hVISA) These are VISA strains in which subpopulations display variable rather than uniform susceptibility to vancomycin.
3. *High-level vancomycin-resistant S. aureus* (VRSA) (MIC ≥ 16 mcg/mL) The mechanism is plasmid-mediated transfer of the *vanA* gene cluster from enterococci with vancomycin resistance (via mobile genetic elements).

The optimal antimicrobial regimen for VRSA strains is unknown. Alternatives to vancomycin include quinupristin-dalfopristin, linezolid, daptomycin and telavancin.

Coagulase-negative Staphylococcus

Most CoNS strains are methicillin-resistant and the drug of choice for treatment is vancomycin. Rifampin or gentamicin can be added to increase the antimicrobial efficacy. The infected catheter or shunt should be removed for complete cure.

Table 2 Recommended antimicrobial agents used in the parenteral treatment of serious *S. aureus* infection

I. Initial empirical treatment when susceptibility of organism is unknown		
Drug of choice	Vancomycin + nafcillin or oxacillin \pm gentamicin	For life-threatening infections (i.e., septicemia, endocarditis, CNS infection)
	Nafcillin or oxacillin	For nonlife-threatening, community-acquired infection (e.g., skin infection, cellulitis, osteomyelitis, pyarthrosis) when prevalence of MRSA is low
	Clindamycin	For nonlife-threatening, community-acquired infection when prevalence of MRSA is high
	*Vancomycin	For nonlife-threatening, hospital-acquired infections
II. Treatment of methicillin-susceptible, penicillinase-resistant <i>S. aureus</i> (MSSA)		
Drug of choice	Nafcillin or oxacillin	–
Alternatives	<ul style="list-style-type: none"> • Cefazolin • Clindamycin • Ampicillin + sulbactam 	–
	*Vancomycin	For penicillin and cephalosporin allergic patients
III. Treatment of methicillin-resistant <i>S. aureus</i> (MRSA)		
A. Hospital associated (multidrug resistant)		
Drug of choice	Vancomycin \pm gentamicin or \pm rifampin	
Alternatives: Sensitivity test should be done before using these drugs.	<ul style="list-style-type: none"> • Trimethoprim-sulfamethoxazole • Linezolid • Quinupristin-dalfopristin 	
B. Treatment of community-acquired MRSA (not multidrug-resistant)		
Drug of choice	Vancomycin \pm gentamicin (or \pm rifampin)	For life-threatening infections
	Clindamycin (if strain susceptible)	For pneumonia, septic arthritis, osteomyelitis, skin or soft tissue infections
Alternative	*Vancomycin	
IV. Vancomycin-intermediately susceptible (MIC 4–8 μ g/mL) and vancomycin-resistant <i>S. aureus</i> (>16 μ g/mL)		
Drug of choice	Optimal therapy is unknown. Dependent on in vitro susceptibility test results. Various drugs which can be tried are: <ul style="list-style-type: none"> • Linezolid • Daptomycin • Quinupristin-dalfopristin • Telavancin 	
Alternative	<ul style="list-style-type: none"> • Vancomycin + linezolid \pm gentamicin • Vancomycin + trimethoprim-sulfamethoxazole 	

*Serum levels of vancomycin should be monitored, with peak concentrations.

PREVENTION

There are no approved antiStaphylococcal vaccines currently in the market. Handwashing with a detergent containing an iodophor, chlorhexidine or hexachlorophene is the most effective measure to prevent the spread of staphylococci. Constant surveillance for nosocomial Staphylococcal infections and careful attention to isolation procedures should be done in hospitals. Health-care workers identified as intranasal carriers of epidemic strain are treated with topical mupirocin and in some cases oral rifampin. Barrier precautions (gloves and gowns) minimize the contact with infected wounds, secretions and dressings. During an epidemic, all full-term infants in nursery are bathed with 3% hexachlorophene immediately after birth and the daily thereafter until discharge. Recurrent Staphylococcal furunculosis is treated with hexachlorophene washes, appropriate oral antimicrobial and nasal mupirocin. To prevent Staphylococcal food poisoning, individuals with Staphylococcal infections of the skin should not be allowed to prepare or handle the food. Once prepared, food should be eaten immediately or refrigerated appropriately to avoid the multiplication of organisms.

PROGNOSIS

Timely treatment with appropriate antibiotics reduces the morbidity and mortality. Without treatment, Staphylococcal septicemia has a mortality rate of more than 80%. A total leukocyte count less than 5,000/cumm or a polymorphonuclear leukocyte response of less than 50% is a grave prognostic sign. Prognosis is affected by various host factors like age, nutrition, immunocompetence and the presence of other debilitating diseases.

IN A NUTSHELL

1. *Staphylococci* are aerobic or facultative anaerobic, catalase-positive, nonmotile, nonsporulating, gram-positive cocci that are ubiquitous in the environment.
2. Two species commonly associated with Staphylococcal disease in human are *S. aureus* and *S. epidermidis*.
3. *Staphylococci* are responsible for millions of community-acquired and health-care-associated infections.
4. Methicillin-resistant *S. aureus* has now become endemic in developing countries and can cause both hospital associated and community-acquired infections.
5. *Staphylococci* produce several virulence factors which can cause disease by either tissue invasion or through toxins.
6. *Staphylococci* can affect any system of the body and the infection ranges from trivial skin infection to lethal invasive disease.
7. The gold standard for diagnosis of Staphylococcal infection is isolation of the organism in cultures of infected specimen.
8. Treatment should be started with an antibiotic depending upon the severity of infection and the Staphylococcal susceptibility pattern of the area. Skin and soft tissue infection can be managed by oral antibiotics and drainage. For severe infections, parenteral therapy is indicated.
9. Constant surveillance for nosocomial Staphylococcal infections and careful attention to isolation procedures should be done in the hospitals. Handwashing is an effective measure to prevent the spread of infection.
10. Timely treatment with appropriate antibiotics reduces the morbidity and mortality. Vancomycin-resistant strains have been reported recently. This emphasizes the importance of rational use of antibiotics, isolation of the causative organism and its susceptibility testing.

Chapter 29.12

Neisseria Infections

Vidushi Mahajan

The two most important *Neisseria* infections are meningococcal disease, also known as epidemic cerebrospinal fever, caused by *Neisseria meningitidis* and gonorrhea caused by *Neisseria gonorrhoeae*. Incidence in India is not exactly clear owing to inadequate surveillance and sparse laboratory support for diagnosis. Meningococcal infections are more frequent in northern states of India. There have been numerous outbreaks of meningococcal disease in India, most recently in 2008–09 from North Eastern states, all attributable to serogroup A. As reported from sexually transmitted disease (STD) clinics, gonorrhea prevalence in Indian children varies between 5% and 10%.

NEISSERIA MENINGITIDIS

Etiology

Neisseria meningitidis has emerged as the third most common etiology of bacterial meningitis in Indian children below 5 years. It is a Gram-negative Diplococcus, seen as kidney-shaped pairs with adjacent sides flattened on Gram staining. *N. meningitidis* is fastidious. Growth occurs in a moist environment at 35–37°C in a 5–10% carbon dioxide atmosphere. Growth is readily supported by chocolate, blood, and Mueller-Hinton media.

Meningococci are commensal colonizers of the nasopharynx. Individuals who harbor these bacteria act as a reservoir of the bacteria. Humans are the only natural reservoir. The incubation period varies 3–4 days (range 1–10 days). Males are slightly more predisposed. Risk factors include young age (more than half cases occur in children less than 2 years), poor hygiene and overcrowded living conditions (e.g., military barracks). Indian Armed Forces is a high-risk group and suffers from 9–10 cases of meningococcal disease per year.

Pathogenesis

N. meningitidis is acquired mainly by the respiratory route. Invasion occurs following infection by new noncommensal strains or sometimes, facilitated by existing viral respiratory tract infection. Meningococci and gonococci produce an IgA protease that helps in colonization of mucous membranes by cleaving the proline-rich hinge region of secretory IgA. Meningococci invade nonciliated epithelial cells through their type IV pili. The pili attach to CD46 proteins on the epithelial cell surface which leads to cytoskeletal rearrangements in the host cell and endocytosis. Meningococci pass through the epithelium and enter the bloodstream. Serum antibody against meningococcal antigens, if present, can block this spread by complement-mediated bacterial lysis. Absence of antimeningococcal antibody is associated with development of meningococcemia. Two additional characteristics of meningococci contribute to its pathogenicity: its polysaccharide capsule and an iron scavenging system which uses host transferrin and lactoferrin.

Meningococcemia is associated with an acute inflammatory response including vasculitis and disseminated intravascular coagulation (DIC). There is activation of inflammatory cytokines (IL-1, IL-6, and TNF α) and of both the extrinsic and intrinsic pathways of coagulation. Blockage of small vessels by leukocyte-rich fibrin clots result in focal hemorrhage and necrosis in major organs particularly skin, heart, central nervous system, adrenals. Myocarditis occurs in more than 50% of patients. Diffuse adrenal hemorrhage without vasculitis known as *Waterhouse-Friderichsen syndrome* may also be seen.

Persons with primary complement, properdin, factor D, or terminal-component deficiency are at increased risk of developing meningococcemia. Recurrent infection is more common with terminal component deficiencies than with properdin deficiency. Also, increased risk is seen with the acquired complement deficiencies that occur in patients with nephrotic syndrome, vasculitis and chronic liver disease. Host factors like presence of factor V Leiden exacerbates *purpura fulminans* (prominent petechia/purpura with hypotension) but may not affect mortality.

Clinical Disease

Invasive meningococcal disease can have protean manifestations, like bacteremia alone, meningococcemia (sepsis), and meningitis with or without meningococcemia. Occult meningococcal bacteremia usually has nonspecific signs mimicking minor viral infections. This presentation may resolve spontaneously without antibiotics, or can lead to meningitis. Meningitis, the most common invasive meningococcal manifestation, presents with lethargy, headache, photophobia, vomiting, and signs of meningeal irritation.

Acute meningococcemia begins with nonspecific viral-like illness with fever, headache, myalgias, vomiting, and diarrhea. Often a maculopapular rash heralds the serious illness. The progression of serious disease may happen rapidly over hours to metabolic acidosis, renal failure, adrenal hemorrhage, DIC, septic shock, and coma. The dissemination may also involve joints (suppurative arthritis), pneumonia, and purulent pericarditis/myocarditis. In the recent epidemic reported from Shillong, (N = 110) following signs were recorded among children with invasive meningococcal disease: Fever (100%), headache (56%), vomiting (54%), altered sensorium (26%), purpura/petechiae (24%), seizures (9%) and excessive crying (5%). Meningeal signs were present in 78% and bulging anterior fontanel in 23% below the age of 18 months. Shock was seen in 38%.

For surveillance purpose the case definitions for probable and confirmed meningococcal disease in Indian setup have been proposed. *Probable case* includes suspected case of acute or bacterial meningitis and positivity for gram-negative Diplococci or ongoing epidemic or with Petechiae/purpura. *Confirmed cases* should have suspected or probable case of acute meningitis and cerebrospinal fluid (CSF)-positivity for *N. meningitidis* or culture-positivity for *N. meningitidis* in CSF or blood.

Outbreak Identification

Outbreak in India is defined as an attack rate greater than or equal to 5-fold higher than that seen in previous years in the same area, or if no data are available for that same area, an attack rate that is greater than or equal to 5-fold higher than that seen in similar areas OR probable and confirmed cases is greater than 5 cases/100,000 over a 3-month period OR incidence (probable or confirmed cases) increases for 3 consecutive weeks in the same area OR attack rate of greater than 3 cases of meningococcal disease in less than 3 months among persons residing in the same area who are not close contacts of each other, with a primary disease attack rate of greater than 10 primary cases/100,000.

Complications

Complications seen are due to meningococcemia and meningitis *per se* and immune complex-mediated which become apparent in the second week after the onset of illness. Suppurative complications include raised intracranial pressure (28%), coagulopathy (16%) and hepatopathy (10%) as seen in the recent epidemic from North-East. Herpes labialis was observed in 9% of cases. Mortality was high in those with metabolic complications of meningococcemia: syndrome of inappropriate antidiuretic hormone (SIADH), diabetes insipidus and cerebral salt wasting (13%). Meningococcal purpura fulminans were seen in 4.5% and less than 2% had subdural empyema and optic neuritis. Mortality was 6.4%.

Immune complex-mediated complications include arthritis and cutaneous vasculitis (erythema nodosum). The arthritis is mono or oligoarticular, involving large joints. Long-term sequelae are uncommon. Fever persisting beyond 7 days in a child with meningococcal illness should alert the physician to the possibility of immune complex-mediated complications.

Approach to Diagnosis

Diagnosis of meningococcal disease rests on isolation of the meningococci from blood, CSF, or synovial fluid. Nasopharyngeal isolation does not imply invasive disease. Prior antibiotic use, which is common in India, reduces the chances of positive culture. Meningococci sometimes can be identified in skin scrapings of petechial lesions. Bacteria may be seen on Gram staining of the buffy coat layer, of a centrifuged blood sample. Diagnosis is also supported by detection of meningococcal antigen in CSF by rapid latex agglutination tests, especially in the setting of partially treated infections or negative cultures. Antigen tests using serum or urine are not recommended. Polymerase chain reaction (PCR) in CSF/blood is now available at a few centers in India.

Other laboratory findings include anemia, neutropenia or leukocytosis with increased band forms, thrombocytopenia, hematuria and proteinuria. Patients with DIC have hypoalbuminemia, metabolic acidosis (high serum lactate) and deranged coagulation studies.

Differential Diagnosis

Meningococcal infection can have overlapping features with sepsis, meningitis, Rickettsial infections and bacterial endocarditis. Encephalitis and viral infections with echoviruses (particularly types 6, 9, and 16), coxsackieviruses (primarily types A2, A4, A9, and A16) may have to be ruled out. Autoimmune disorders like Henoch-Schönlein purpura, hemolytic-uremic syndrome, Kawasaki disease, idiopathic thrombocytopenic purpura, and drug rash can mimic meningococcal disease.

Management

Crystalline Penicillin is the drug of choice. Cefotaxime or ceftriaxone are acceptable alternatives in case of nonavailability or drug resistance. Chloramphenicol (75–100 mg/kg/24 hours divided q 6 hours IV) is used for children allergic to β -lactam antibiotics. Therapy is recommended for at least 7 days. Shock necessitates treatment with normal saline and inotropes. Children with fulminant meningococcemia with refractory shock may require hydrocortisone due to adrenal insufficiency. Extracorporeal membrane oxygenation has been used with limited success.

Outcome

Deafness occurs in 5–10% of children with meningococcal meningitis. Cerebral thrombosis leading to cerebral infarction can occur in severe cases. Rare neurologic sequelae like focal deficits, seizures, ataxia and obstructive hydrocephalus may be seen 3–4 weeks after onset of illness. Case fatality in severe disease forms like pyogenic meningitis or septicemia is 5–25% despite advancements in pediatric critical care.

Prevention

Vaccination (Also see Chapter 23.21 on Meningococcal Vaccines)

Routine immunization is not recommended currently. Vaccine is recommended only during outbreaks, in high risk children and international travelers. The two meningococcal conjugate vaccines (MCVs) licensed in India are: firstly a quadrivalent (A, C, W-135, Y) polysaccharide-protein conjugate vaccine MenACWY-D, Menactra[®]. Single dose of 0.5 mL IM is recommended in children above 2 years age. Two-doses of this vaccine is recommended in children aged

9–23 months. Studies suggest that effectiveness is 80% to 85% within 3 to 4 years after vaccination. Side effects include pain, swelling, and rare reports of Guillain-Barré Syndrome especially in adolescents. When MenACWY-D and PCV13 are administered concomitantly, interference in PCV13 immune responses was noted especially in patients with asplenia. Hence, it is recommended that at least one month interval should be kept between PCV13 and MenACWY-D, and PCV13 should be administered first. Second MCV is a monovalent serogroup A conjugate vaccine (PsA-TT, MenAfriVac[®]). The vaccine is immunogenic in adults but is unreliable in children younger than 2 years.

Mass Reactive Vaccination

In India it is carried when disease incidence is 10 cases/100,000 in a given district. Mass immunization with bivalent (A + C) polysaccharide vaccine was carried as a pilot project in India during the Meghalaya outbreaks.

Care of Contacts

Chemoprophylaxis is given to close contacts to eliminate nasopharyngeal carriage, preferably within 24 hours of contact with an index case. Ciprofloxacin is the drug of choice since only a single oral dosing is needed. Ceftriaxone is another alternative (125 mg stat IM for children < 12 years; 250 mg stat IM for > 12 years of age). Children may be given rifampin (10 mg/kg orally q 12 hours for a total of four doses; maximum dose: 600 mg; 5 mg/kg/dose for infants < 1 month of age)). Mass chemoprophylaxis is not considered to be useful or epidemiologically cost effective.

NEISSERIA GONORRHOEA

Gonorrhea is the most frequent sexually transmitted infection (STI) found in sexually abused children. It is an infection of the mucus membranes of the genitourinary tract and rarely, rectum, oropharynx and conjunctiva. Risk factors include unprotected sex, multiple sexual partners, homosexuality, poverty, presence of other STI. Gonococcal infection in the neonate results from perinatal exposure during birth. Universal screening for gonorrhea is not advised since gonococcal infections in females are commonly asymptomatic. For preadolescent girls, vaginitis is the most common symptom. Disseminated gonococcal infection may present as *tenosynovitis-dermatitis syndrome*, characterized by fever, rash, and polyarthralgia involving the wrists, hands, and fingers; or as *suppurative arthritis syndrome*, in which systemic signs are not marked and monoarticular arthritis, often involving the knee, occurs. Due to the legal implications involved, culture is the preferred method of diagnosis. Specimens from normally unsterile sites are streaked on a selective (e.g., Thayer-Martin or Martin-Lewis) medium and specimens from sterile sites are streaked on nonselective (e.g., chocolate agar) medium. Nucleic acid amplification testing (NAAT) is recommended under special circumstances. Serology is not recommended because it fails to denote an active infection. Cephalosporins are the sole class of antibiotics recommended for the treatment of *N. gonorrhoeae* infections. All children found to have gonorrhea should be tested for other STDs, including Chlamydia, syphilis, and HIV.

Treatment guidelines are summarized in **Box 1**.

BOX 1 Treatment of gonorrhea (CDC 2010)

1. For uncomplicated gonococcal infection: (Weight < 45 kg)
vulvovaginitis, cervicitis, urethritis, pharyngitis, proctitis
Ceftriaxone 125 mg IM in a single dose
2. For bacteremia/arthritis (Weight < = 45 kg)
Ceftriaxone 50 mg/kg IM or IV (max. 1 g) once a day for 7 days
3. For bacteremia/arthritis (Weight > 45 kg)
Ceftriaxone 50 mg/kg IM or IV (max. 1g) once a day for 7 days.

IN A NUTSHELL

1. Invasive meningococcal disease presents as meningitis, or meningococemia (sepsis) or both. It occurs in endemic as well as epidemic forms.
2. It is caused by gram-negative *Diplococcus*, *Neisseria meningitidis*, which are normal commensals of the nasopharynx in 5–10% of the population.
3. Young age (children < 2 years), overcrowded living conditions and complement deficiencies (both inherited and acquired) are important risk factors.
4. Children usually present with fever, headache, altered sensorium, purpura/petechiae, meningeal signs and seizures. More than one-third of the patients develop shock during course of illness. Complications due to inflammation include pneumonia, raised intracranial pressure, coagulopathy, hepatopathy, diffuse vasculitis, DIC, Waterhouse-Friderichsen syndrome, purpura fulminans and subdural empyema. Immune complex mediated complications include arthritis and erythema nodosum.
5. Diagnosis of meningococcal disease rests on isolation of meningococci from blood, CSF, or synovial fluid by culture, latex agglutination, or PCR and skin scrapings of petechial lesions.
6. Important differential diagnosis includes sepsis, Rickettsial infections, bacterial endocarditis, autoimmune vasculitides, coxsackie and echovirus infections.
7. Drug of choice is Penicillin G (250,000–400,000 U/kg/24 hours divided q 4–6 hours IV). Alternatively, cefotaxime or ceftriaxone maybe used. Isolation for at least 72 hours is advised.
8. Ciprofloxacin/ceftriaxone is used for chemoprophylaxis in close contacts. Meningococcal vaccination is recommended in select groups and in outbreak situations.

Chapter 29.13

Pseudomonas Infections

Nupur Ganguly

Pseudomonas aeruginosa is an opportunistic pathogen of the Pseudomonadaceae family and causes infections usually in immunocompromised host. It is one of the most important causes of nosocomial infection. Its ubiquitous presence and minimal nutritional needs causes easy colonization and develop reservoirs in sinks or respiratory equipment in hospital setting. Prolonged hospital stay, mechanical ventilation, and central line catheters cause breach in host defense and predisposes to *Pseudomonas* infection. *Pseudomonas aeruginosa* has a wide potential to develop resistance to multiple antibiotics by various mechanisms and inappropriate empirical therapy increases the possibility of development of such resistance. Multidrug resistance (MDR) *Pseudomonas*, resistant to at least 3 out of 4 classes of antibiotic, i.e., antipseudomonal penicillin (piperacillin, cephalosporins), Carbapenems, fluoroquinolones and aminoglycoside, is an emerging challenge for associated mortality, morbidity and high cost of therapy.

EPIDEMIOLOGY

Pseudomonas aeruginosa is a gram-negative nonfermenting aerobic bacillus (can grow anaerobically if nitrate is available). It is mostly present in moist environment, and easily colonise in sinks, respiratory equipment, mops and disinfectants; even it can survive in distilled water. Being an opportunistic pathogen impaired host defense is the prerequisite to develop infection. These infections further spread from patient to patient on the hands of hospital personnel, by direct patient contact or with the contaminated reservoirs. In developing countries *Pseudomonas* is a common pathogen in burn wound, febrile neutropenia and patients undergoing chemotherapy and causes most serious infection in ventilator associated pneumonia. It is also the leading cause of chronic lung infection and respiratory failure in cystic fibrosis.

PATHOGENESIS

Pseudomonas aeruginosa has various invasive and virulence factor causing acute and chronic infection. The surface virulence factor (flagella, pili and lipopolysaccharide) helps in attachment, colonization and invasion. Secreted virulence factor (mucoid, exopolysaccharides, exotoxin A and proteases) damages tissue and produces cytokines causing tissue damage. Impaired host defense mechanism further contributes to the virulence and chronicity of infection.

Its single polar flagellum helps in motility and adhesiveness to the cell surface for initiation of infection. The pili present in the outer surface membrane of *Pseudomonas*, attaches to the epithelial cells at the site of colonization and forms a nidus for local infection. In immunocompromised host it becomes locally invasive and cause systemic infection. Several toxins produced by *Pseudomonas* counteract the host defense mechanism. Among them exotoxin A causes tissue necrosis, Type III secretion system (TTSS) injects four types of exotoxin (ExoU, ExoS, ExoT, and ExoY). ExoU, are more toxic, and are associated with poor outcome and increased mortality in ventilator associated pneumonia (VAP). Pyocyanin is responsible for greenish sputum in *Pseudomonas* infection, causes epithelial and endothelial damage to the lung tissue in acute infection. Like majority of other organisms, *P. aeruginosa* needs iron to sustain growth. Pyochelin a derivative of pyocyanin is a siderophore helps in deriving iron from the host cell for bacterial growth. *Pseudomonas aeruginosa* in presence of large bacterial mass communicates with each other through

the system of quorum sensing (QS), in response they secrete inflammatory mediators increasing the virulence of the organism. Quorum sensing system also helps in the formation of biofilm.

CLINICAL FEATURES

Pseudomonas aeruginosa rarely infects the healthy tissues, however, in presence of impaired host response, it can infect any tissue. Among them the most common infections are as follows:

Bloodstream Infection

Disseminated bacterial infection is seen in burns, neutropenia and malignancies where patient is undergoing chemotherapy. It has a grave prognosis and the mortality is about 50%. The clinical presentation of septicemia is same as with other gram-negative infection and patient may present in shock. A typical vasculitic skin lesion which differentiates from other gram-negative infection is ecthyma gangrenosum. They are small painful hemorrhagic lesion with necrosis, pink in color to start with and become gangrenous.

Ventilator Associated Pneumonia

In ventilated patient initial slow colonization of *Pseudomonas aeruginosa* may lead to rapid fulminant infection. Patient presents with fever, chill, cough, cyanosis and tachypnea, X-ray shows bilateral opacities often with cavity formation. Isolation of the bacteria from sputum and bronchoalveolar lavage is diagnostic.

Urinary Tract Infection

Prolonged use of catheter, instrumentation and urinary tract obstruction predisposes to *Pseudomonas* infection. They have a complicated course and needs prolonged treatment.

Pseudomonas Dermatitis

Though less severe, community infections occur as folliculitis following bath in swimming pools, paronychia, and toe web infection seen with prolonged exposure to water. Puncture wound infection through shoes can give rise to serious infection. The bluish or greenish color pus is suggestive of *Pseudomonas* infection and is due to the pigment pyocyanin.

Eye and Ear

Pseudomonas is a predominant cause of otitis externa and severe ophthalmic infection (corneal keratitis) following prolonged use of contact lens.

Cystic Fibrosis

Chronic infection is commonly seen in patients with cystic fibrosis. In cystic fibrosis mucoid strains of *Pseudomonas* produce large amount of exopolysaccharide (alginate) to form biofilm. The biofilm helps in anchoring the bacteria to respiratory tract, impairs the ciliary movement facilitating colonization. Initial colonizations with nonmucoid strains are slowly replaced with the mucoid strain. These mucoid strains resist phagocytosis and host immune response by the biofilm formation leading to chronicity of the disease with frequent exacerbation. Due to repeated use of antibiotics the organism develops resistance to multiple antibiotics.

DIAGNOSIS

Clinical suspicion and certain clues like features of sepsis developed in immunocompromised host in ICU setting, greenish or bluish pus in abscess or greenish sputum in cystic fibrosis are suggestive of *Pseudomonas* infection. Due to easy colonization, simple isolation of the organism from the biological tissue is not diagnostic. Isolation of the bacteria from the central body fluid, external devices is diagnostic in the high risk individual.

MECHANISM OF RESISTANCE

P. aeruginosa causes resistance by various mechanisms leading to MDR infection. Different mechanisms of resistance are discussed below:

Altered Porins

It does not have the usual trimeric porins characteristic of enteric bacteria, instead it has monomeric porin, which reduces the membrane permeability of the drug leading to very slow entry. The mechanism operates for chloramphenicol and aminoglycosides.

Active Efflux

Active efflux system (MexAB-OprM) causes expulsion of the antibiotic out of the cell and thus increasing the Minimum inhibitory concentration (MIC) of the drug. In *Pseudomonas* infection efflux mechanism is the major factor contributing resistance to aminoglycosides, fluoroquinolones, and many beta-lactams. It is either chromosomal or plasmid mediated.

Bacterial Destruction

Bacterial destruction of beta-lactams by beta-lactamases enzyme is another common method of resistance in *Pseudomonas* infection. They are plasmid encoded mutated enzymes. Carbapenemases have wider spectrum of activity and not only hydrolyses carbapenems (meropenem, doripenem and imipenem) but also other beta lactams, e.g., cefotaxime and ceftazidime. They cannot hydrolyze monobactam (aztreonam) and are not inhibited by clavulanate.

Mutation

Fluoroquinolone resistance is caused by mutation of DNA gyrase.

Often all these mechanisms are present simultaneously causing MDR phenotypes. In cystic fibrosis formation of biofilm is also a major contributing factor for drug resistant infection.

TREATMENT

Due to the high mortality of *Pseudomonas* infection empirical therapy is often initiated. The choice of antibiotic in empirical therapy should depend on the age, site of infection, local resistance and prior use of certain antibiotics, including broad-spectrum cephalosporins, aminoglycosides, carbapenems, fluoroquinolones and hospital culture data. Combination therapy for empiric treatment is indicated in certain high risk patients, in severe infection and it should be prompt, as delay in therapy may lead to increased mortality. All infected catheters and devices should be removed, and abscesses should be drained whenever possible. The following antibiotics usually have reasonably good activity against *P. aeruginosa* and can be used alone as single agents if isolates are susceptible by in vitro testing: (a) beta-lactam and beta-lactamase inhibitor: ticarcillin-clavulanate, piperacillin-tazobactam; (b) Cephalosporins: ceftazidime, cefoperazone, cefepime; (c) Monobactam: aztreonam; (d) Fluoroquinolones: ciprofloxacin, levofloxacin; and (e) Carbapenems: meropenem, doripenem, imipenem. Doripenem has the least resistance amongst the three.

Alternative Antibiotics

When choice is limited in MDR *P. aeruginosa* infection, intravenous colistin and polymyxin B are alternative drugs. Colistin has a tendency for ototoxicity and nephrotoxicity, and requires dose adjustment in impaired renal function.

Adjunctive Antibiotics

Aminoglycosides (gentamicin, tobramycin and amikacin) should not be used as monotherapy due to their poor efficacy. They are effective when used in combination with the first line drugs in serious infection.

Inhaled Antibiotics

Inhaled tobramycin, gentamicin, polymyxins and colistin may be used in cystic fibrosis as an adjunct therapy for pneumonia and to prevent bronchiectasis.

Efflux Pump Inhibitors (EPI)

They are the newer modalities of treatment in the pipeline. These antibiotics target the active efflux mechanism of drug resistance.

COMBINATION VERSUS MONOTHERAPY

For combination therapy a beta-lactam is combined with aminoglycoside in the absence of any contraindication for the use of aminoglycoside, otherwise fluoroquinolone can be an alternative choice. Indications of combination therapy are severe sepsis or septic shock; neutropenic patients with bacteremia; burn patients; and endocarditis. However, controversy exists regarding the superiority of combination to monotherapy. In a meta-analysis of randomized control trial including immunocompromised patients with documented sepsis, combination therapy has not shown any reduction in mortality.

IN A NUTSHELL

1. *Pseudomonas aeruginosa* is an opportunistic pathogen of the Pseudomonadaceae family and causes infections usually in immunocompromised host.
2. It is one of the most important causes of nosocomial infections including, bacteremia, ventilator associated pneumonia, catheter infections.
3. *Pseudomonas* is an important infection in children with cystic fibrosis.
4. Piperacillin-tazobactam; ceftazidime, cefoperazone, cefepime; aztreonam; ciprofloxacin, levofloxacin; and meropenem, doripenem, imipenem have good activity against *Pseudomonas*.
5. Multidrug resistance (MDR) *Pseudomonas*, resistant to at least 3 out of 4 classes of antibiotic, i.e., antipseudomonal penicillin (piperacillin, cephalosporins), carbapenems, fluoroquinolones and aminoglycoside, is an emerging challenge.

Chapter 29.14

Leptospirosis

Janani Sankar

Leptospirosis is an infectious disease caused by pathogenic organisms belonging to the genus *Leptospira*, and transmitted directly or indirectly from animals to humans. Human-to-human transmission occurs rarely. The disease can range from a subclinical infection to a serious multi organ involvement.

ETIOLOGY

Leptospira are aerobic bacteria. *Leptospira interrogans* is the pathogenic species that causes the disease and it has more than 250 serovars and each serovar can cause different syndromes. For example, the serovar *Leptospira icterohaemorrhagiae* usually causes hepatitis.

EPIDEMIOLOGY

Cattle, buffaloes, horses, sheep, goat, pigs, dogs and rodents are common reservoirs of leptospires. Rodents were the first recognized carriers of leptospirosis. They are the only major animal species that can shed leptospires throughout their lifespan without clinical manifestations, i.e., prolonged carrier state. They are incriminated as a primary source of infection to human beings. Although serovars icterohaemorrhagiae, Copenhageni, Grippotyphosa and Ballum have been often associated with rodents, other serovars like Pomona, Canicola and Hebdomadis have also been isolated.

PATHOGENESIS

Leptospires enter humans through abrasions and cuts in the skin or through mucous membranes. After penetration to the blood stream they cause endothelial lining damage of blood vessels and also cause ischemic damage of end organs.

CLINICAL FEATURES

Anicteric Form

The clinical presentation of leptospirosis varies widely. It can range from an acute febrile illness to a severe syndrome of multiorgan dysfunction. The more common, mild, anicteric form of the disease is characterized by nonspecific symptoms such as fever, headache, chills and severe myalgia restricting mobility. It may closely mimic acute infectious polyradiculomyelitis. CPK enzyme levels are usually very high. It may present with lymphadenopathy and generalized maculopapular rash mimicking mucocutaneous lymph node syndrome. Other manifestations include meningoencephalitis where children have severe headache and neck stiffness. CSF shows mildly elevated protein and lymphocytosis. Neuroimaging may show leptomeningeal enhancement. CSF dark field microscopy for leptospires may be positive.

Similar to enteroviral infections, it can cause myocarditis which is more common in infants and toddlers. A short febrile illness with disproportionate tachycardia, muffled heart sounds and cardiomegaly with or without raised CPK MB is usually the clinical picture. Apart from parenteral crystalline penicillin these children need inotropes and hemodynamic monitoring. Polyserositis is usually seen in the form of pleural effusion, pericardial fluid, ascites and gallbladder wall edema. This is usually associated with reduced serum albumin and occasionally these fluids may test positive for dark field microscopy. Transient glomerular dysfunction which closely mimics nephrotic syndrome is seen in

some children. Hepatorenal syndrome is a more serious condition which may require peritoneal or hemodialysis. It can involve the eyes and cause severe conjunctival congestion and uveitis.

Weil Syndrome (Icteric Form)

The illness closely mimics acute viral hepatitis and the probable differentiating features may be the presence of polyserositis and cholecystitis. This is a severe form of the infection, occurs less commonly in children and can sometimes coexist with hepatitis A infection. When it coexists with hepatitis A infection the severity and the duration of illness is longer. Renal manifestations are common, with abnormal urine analysis (hematuria, proteinuria, and hyaline and granular casts) and azotemia, which is often associated with oliguria/anuria. Acute renal failure occurs in a few cases and is the most common cause of mortality. Both acute renal failure and jaundice are less common in children than in adults.

APPROACH TO DIAGNOSIS

A high index of suspicion is usually required to diagnose Leptospirosis. It is usually suspected in the clinical context of fever with myalgia with history of contact with animals. A *confirmed case* of leptospirosis is one where the clinical specimens are culture positive for leptospira or the clinical symptoms are compatible with the disease and there is seroconversion or a fourfold rise in microscopic agglutination titer between acute and convalescent sera (taken at least 2 weeks apart and studied in same laboratory). A *presumptive case* is one where the clinical symptoms are compatible with the disease and microscopic agglutination titer is 1:100 or greater, there is a positive macroscopic agglutination slide test reaction on a single serum specimen obtained after onset of the symptoms, or there is a stable microscopic agglutination titer of 1:100 or more in two or more serum specimens obtained after onset of symptoms.

Modified Faine's criteria (Table 1) used for diagnosis of leptospirosis in adults, has also been found to be useful in older children. The Indian Leptospirosis Society has also laid down certain criteria for clinically suspecting leptospirosis. According to these criteria, leptospirosis should be suspected in a child presenting with a history of abrupt onset of high fever (> 39°C) and bodyache/headache, with any one or more of the following features: (i) jaundice, (ii) oliguria, (iii) cough and breathlessness, (iv) hemorrhagic tendency, and (v) signs of meningeal irritation or altered sensorium or convulsions.

Laboratory Investigations

The total count is usually higher with polymorphonuclear predominance and toxic granulation in the neutrophils. The platelet count is usually reduced.

C-reactive protein (CRP) may be positive and serum albumin levels may be low, more so in children with polyserositis. Bilirubin and liver transaminases are raised in icteric leptospirosis. Creatinine phosphokinase (CPK) may be raised in children presenting with myalgia and Creatinine Phosphokinase Muscle-Brain Fraction (CPK-MB) may be raised in children with myocardial involvement.

Serological Tests

Serological tests are usually preferred for confirmation of diagnosis. Detection of IgM antibodies during the second week of illness is the most sensitive test. A single high or a fourfold rise in IgG titer in paired samples is also suggestive of the infection. Slide agglutination method, Dri-Dot assay, LEPTO Dipstick, latex agglutination, complement fixation assay, indirect immunofluorescent test, and indirect hemagglutination test are the other tests with high sensitivity. DNA hybridization techniques or nucleic acid amplification procedures, including polymerase chain reaction

Reproduced with permission from: Prof S Shivakumar, Chennai

(PCR) and Warthin-Starry Silver staining polymerase chain reaction and immunohistochemical methods can be used to detect the presence of leptospira in body fluids or culture supernatants. The microscopic agglutination test (MAT) (serogroup-specific assay) using live antigen suspension of leptospiral serovars is the gold standard. This test is not helpful for diagnosing leptospirosis during the acute illness; however, it remains important for epidemiological research purposes. The test is read by dark-field microscopy for agglutination and the titers are determined; a four-fold or greater increase in titer in paired sera is confirmative. Agglutinins usually appear by the second week of illness and reach the maximum titer by the 4th week. Due to lack of specific live serovars MAT is not regularly done. MAT titer of 1:100 is usually seen in the general population in endemic area and does not suggest active infection. High titers are usually required to make a diagnosis of active disease.

Demonstration of Organism in Cultures

Though not easily available and not used in practice, demonstration of the organisms in the patient's blood and culture of the organism can be used for diagnosis before the second week of the illness. *Leptospira* can be recovered from the blood or CSF during the first 10 days of illness and from the urine after 14 days.

TREATMENT

Leptospirosis usually responds to oral amoxicillin (50–100 mg/kg/day for 7 days), azithromycin (10 mg/kg/day for 3 days), cefixime (10 mg/kg/day for 7 days) or doxycycline (5–10 mg/kg/day for 7 days). Antibiotic administration especially before the 7th day of illness reduces length of hospitalization and leptospiruria. In children, even late institution of antibiotic treatment has been shown to prevent complications. Treatment with parenteral penicillin 50,000–100,000 U/kg/day is usually reserved for very sick children with meningoencephalitis, myocarditis and renal involvement.

Adequate attention to supportive care, including maintenance of the fluid-electrolyte balance, treatment of cardiovascular collapse, and provision of dialysis for renal failure, are equally important. Frequent monitoring of vital parameters and hemodynamic assessment, careful charting of fluid input and output, and prompt use of ionotropes in patients with hypotension refractory to fluid therapy are important considerations in the management of the disease.

PREVENTION

Prevention is usually achieved by controlling the reservoir or reducing infection in animal reservoir populations such as dogs or livestock. Prevention and control should be targeted at the infection source; and the route of transmission between the infection source and the human host.

It is important to target reduction of animal reservoir populations like rats and immunization of live stocks.

PROGNOSIS

It usually depends upon the type of clinical illness. The milder forms and the anicteric usually respond to oral drugs and recover completely. The severe type with multi organ involvement like acute respiratory distress syndrome (ARDS), myocarditis, liver cell failure and renal failure is usually associated with high mortality.

IN A NUTSHELL

1. Leptospirosis is a zoonosis caused by pathogenic organisms belonging to the genus *Leptospira*, and transmitted directly or indirectly from animals to humans.
2. Rodents are incriminated as a primary source of infection to human beings.
3. The clinical presentation of leptospirosis varies widely. It can range from an acute febrile illness to a severe syndrome of multiorgan dysfunction. Two main forms are anicteric form and icteric presentation (Weil disease).
4. Weil syndrome closely mimics acute viral hepatitis. Polyserositis and cholecystitis are additional features.
5. The microscopic agglutination test (MAT) (serogroup-specific assay) using live antigen suspension of leptospiral serovars is the gold standard for diagnosis.
6. Leptospirosis usually responds to oral amoxicillin, azithromycin, cefixime, or doxycycline.

Chapter 29.15

Plague

Baldev S Prajapati, Rajal B Prajapati, Piyush Gupta

Plague is an infectious disease of rodents which is transmitted to man through the bite of infected ectoparasite (rat-flea) caused by the bacteria *Yersinia pestis*. It is primarily a zoonosis involving rats and rat-fleas with man being an intermediate host. The first mention of plague dates back to 1320 BC. In AD 542, a record 100 million people died of it in Europe. Due to associated high mortality, plague has also been referred to as *black death*. The first reported outbreak of plague in India occurred in the early part of the seventeenth century. Plague often occurs in epidemics and is characterized by rapidly developing infection with severe toxemia and a grave prognosis in the absence of treatment.

There are certain well known world foci from which epidemics have been known to originate, after periods of inactivity. Although the most modern pandemic, occurring at the end of the last century, has continued to decline, outbreaks have emphasized the continued presence of virulent bacteria in India, Cambodia, Vietnam, Indonesia, Africa, Brazil, Argentina, Chile, and Peru. In 2004, India reported a localized outbreak of bubonic plague in the Dangud village, district of Uttarkashi.

ETIOLOGY

The genus *Yersinia* is in the family, enterobacteriaceae and is composed of 11 species. Among them, *Yersinia enterocolitica*, *Yersinia pseudotuberculosis* and *Yersinia pestis* are pathogenic for humans and animals. These organisms usually infect rodents, pigs and birds. Humans are the accidental hosts. *Yersinia pestis* is transmitted by fleas or in aerosols and it is the cause of plague. *Yersinia enterocolitica* and *Yersinia pseudotuberculosis* cause enterocolitis.

Yersinia pestis is a gram-negative nonmotile, nonspore forming, intracellular coccobacillus. The bacteria can be isolated from blood, sputum or enlarged lymph nodes during the active disease. Virulence is determined by antigens V, W, envelope of fraction I, purine synthesis, and production of both exotoxin and endotoxin. The organism has several chromosomal and plasmid related factors. These factors are responsible for its virulence and survival in mammalian hosts and fleas. Its bipolar staining appearance is shared with *Yersinia pseudotuberculosis*. The biochemical reactions, serological tests, phage sensitivity and molecular techniques can differentiate *Yersinia pestis* from *Yersinia pseudotuberculosis*.

EPIDEMIOLOGY

Plague is basically maintained in nature by rats and other rodents. These rodents include mice, skunks, squirrels, gophers, and rabbits. Dogs and cats have also been implicated in human cases. Principal hosts in India are the wild and domestic rats—*Tatera indica* and *Rattus rattus*. Infection persists as a chronic disease of wild rodents and maintained by the insect vector.

Vector

Plague is transmitted by the bite of insect vectors, the most common being the rat-flea, i.e., *Xenopsylla cheopis*. Other uncommon vectors include *X. brasiliensis* and *Diamanus montanus*. The infected flea regurgitates a large number of bacteria into the bloodstream of the host during feeding. When another rat-flea bites the host, it ingests the infected blood. A clot is formed in the proventriculus of the

flea by the action of enzymes produced by both *Y. pestis* (coagulase) and the flea (trypsin). The clot blocks the flea's alimentary tract, propagating bacterial multiplication. When this flea bites another host, it discharges huge numbers of *Y. pestis* into its bloodstream. Formation of clot occurs at low ambient temperatures explaining the abatement of plague epidemic in summer months.

Host and Environment

Plague can occur at all ages and in both sexes. Man does not possess any natural immunity to *Y. pestis*. Asymptomatic carrier state, though rare, is known to occur. Plague epidemics occur more commonly in winter months. During monsoon, heavy rainfall will flood the rat burrows and stop the transmission. Natural or man-made calamities like earthquakes and wars have been found to be associated with outbreaks of plague in the past.

PATHOGENESIS

Humans can acquire plague by (i) bite of an infected flea; or (ii) inhalation of infected droplets from a case of pneumonic plague. In rare cases, the organism may enter through pharynx or conjunctiva. Rat-flea attacks the man only if rats are not available immediately. This situation arises in an epizootic, characterized by death of large number of infected rodents.

The spread among human population occurs by the respiratory route. Airborne droplet nuclei are discharged by the cases suffering from pneumonic plague. Bubonic plague cannot spread from person to person because the bacilli are locked inside the bubo and are not accessible to outside world until the bubo ruptures. Role of asymptomatic carrier in transmission of disease is not clear.

The infected fleas inoculate the organisms into skin of the patient while feeding. These organisms are drained to regional lymph nodes where they replicate and it results in bubonic plague, the most common form of plague. If the patient does not get specific therapy promptly, it may cause bacteremia, resulting in purulent, necrotic and hemorrhagic lesions in several organs. The pneumonic plague is due to inhalation of infected material. The pneumonic plague is highly transmissible type of plague. The domestic cats with pneumonic infection are also responsible for transmission of the disease. Due to high transmissibility and high morbidity as well as mortality, *Yersinia pestis* is considered as an important threat for its use as a biological weapon.

CLINICAL MANIFESTATIONS

Yersinia pestis infection has very wide spectrum of clinical presentation, starting from asymptomatic to severe fatal clinical syndrome. Bubonic plague, Pneumonic plague, Septicemia and Meningitis are main clinical presentations of the disease.

Bubonic Plague

Bubonic plague accounts for 80–90% of cases. There is an incubation period of 2–8 days after a fleabite. From 2–8 days after a fleabite, tender, nonfluctuating lymphadenitis (bubo) develops in regional lymphatics draining the bite area. The development of bubo depends upon the site of inoculation. The inguinal region is the most common site for development of bubo. Axillary and cervical regions are other known areas for its development. A papule, vesicle or ulcer at the inoculation site develops in approximately 25% of cases. Tenderness of the involved nodes is remarkable. It may cause suppuration in about 20% cases. The patient tries to avoid movement or pressure on the bubo. In 90% of cases, the bubo is unilateral and can be up to 10 cm in diameter. Although the onset of fever usually coincides with development of adenitis,

fever can occur days before it. There is a rapid rise in temperature (about 39.4°C) with chills, headache, malaise, anorexia, vomiting, myalgia and prostration during the hematogenous spread from the infected bubo. The skin may show insect bites and scratch marks. Localized cellulitis or abscess at the flea bite site is rare. Endotoxic shock is followed in a few days by death in the absence of specific antibiotics therapy. Purpura and gangrene of extremities may develop in relation to intravascular coagulopathy. Untreated plague has a mortality of about 50%. The death may occur within 2 to 4 days after onset of symptoms.

Pneumonic Plague

Pneumonia (16% of cases) can occur by inhalation (primary plague pneumonia) or by hematogenous seeding of bubonic or septicemic plague (secondary pneumonia). Pneumonic plague is the least common but most dangerous and fatal form of the disease. It may cause chest pain, progressive tachypnea, dyspnea, hypoxia and productive cough. The sputum may be frothy, blood-tinged, hemorrhagic or purulent. Chest X-ray typically shows alveolar infiltrations. In cases related to inhalation of secretions from infected animals or humans, extensive bronchopneumonia with cavities may develop. Primary plague pneumonia can progress quickly and may result in death even on the first day of symptoms. Plague pneumonia develops more commonly in patients with septicemia than in those with bubonic plague.

Other Manifestations

Septicemic plague occurs in 15–25% of cases. It is characterized by severe endotoxemia and multiorgan failure. Untreated, 100% cases are fatal. Even with treatment, the mortality is more than 30% in this group. The abdominal pain, nausea, vomiting and diarrhea like symptoms may be confusing and misleading. Plague can manifest as septicemia without a bubo. Tonsillitis and gastroenteritis are also known to occur in plague. These manifestations may or may not be associated with bubo formation and lymphadenopathy.

Meningitis

Altered sensorium with lethargy, stupor or delirium is common, but meningitis may be a complication of bubonic plague, particularly occurring in individuals who have been inadequately treated. Meningitis is more common in children than in adults. It occurs in 10% of children with plague.

LABORATORY FINDINGS

Leukocytosis in the range of 10,000–20,000/cu mm is common with shift to the left. Staining of clinical specimens (lymph node aspirates, blood, sputum, exudates) with Gram, Wayson or Giemsa stains may reveal characteristics bipolar staining coccobacilli. In patients with pulmonary involvement sputum is purulent and loaded with bipolar staining gram-negative, pleomorphic coccobacilli. Diagnosis can also be made by polychromatic or fluorescent antibody methods, antigen detection, or PCR. Needle aspirate specimens from infected nodes yield growth of organisms in about 75% of patients. *Yersinia pestis* grows in routine culture media, including blood agar, within 48 hours. Culture of blood specimens has positive results in about 60% of children with bubonic plague and in about 100% of those with septicemic plague. Quantitative blood culture data suggest that a bacterial density greater than 10^2 organisms/mL is associated with a greater risk of hypotension and shock. Cerebrospinal fluid in meningitic plague has features typical of bacterial meningitis such as polymorphonuclear leukocytosis and positive Gram stain.

Serological testing is useful retrospectively. Convalescent serum specimens are collected 4 weeks after onset of illness. Passive hemagglutination test, enzyme immunosorbant assay (EIA) and dot EIA have been used to detect immunoglobulin G antibodies against *Yersinia pestis*.

TREATMENT

Patients suspected of having bubonic plague should be placed in isolation until 2 days after starting antibiotic treatment to prevent the potential spread of the disease. Bubonic plague is treated with injection streptomycin 30 mg/kg/day, divided in two doses by intramuscular route for 10 days. Streptomycin is inappropriate for septicemic plague because of its erratic absorption. Gentamicin (2.5 mg/kg IM/IV three times daily), doxycycline (< 45 kg: 4.4 mg/kg/day, divided in 2 doses, IV; > 45 kg: 100 mg every 12 hours IV or 200 mg IV once daily) or chloramphenicol (25 mg/kg (maximum 500 mg) orally or IV four times daily for 10 days) should be preferred for septicemia and meningitis. Another alternate is ciprofloxacin 30 mg/kg/day IV twice daily (20 mg/kg orally twice daily) for 10 days. Resistance and relapses to gentamicin, doxycycline, chloramphenicol and ciprofloxacin are rare. *Yersinia pestis* may be susceptible to penicillin in vivo, but it is ineffective in treatment of human disease and therefore penicillin should not be used. Clinical improvement is noted within 48 h of initiating treatment.

Postexposure Prophylaxis

The close contacts of patients with pneumonic plague should be given post exposure prophylaxis. Contacts of cases of uncomplicated bubonic plague do not require prophylaxis. Antimicrobial prophylaxis is recommended within 7 days of exposure for persons with direct, close contact with a pneumonic plague patient or those exposed to an accidental or terrorist induced aerosol. Tetracycline or doxycycline or TMP-SMZ should be given for 7 days as postexposure prophylaxis.

PREVENTION AND CONTROL

Clinical suspicion during an outbreak should be given paramount importance. The diagnosis of plague should be considered if cases of the following clinical presentations occur in previously healthy patients, especially if two or more cases arise that are linked in time and place:

- Sudden onset of severe, unexplained febrile respiratory illness;
- Unexplained death following a short febrile illness;
- Sepsis with gram-negative coccobacilli identified from clinical specimens.

The level of suspicion of plague depends on local circumstances at the time—in the event of a known or suspected deliberate release, or among contacts of plague cases, the threshold for making a diagnosis of plague should be lower. If plague is suspected, microbiological specimens should be sent for assay, and consideration should be given to initiating empirical treatment pending results.

The bacilli can be demonstrated in a stained smear from bubonic fluid or sputum. Pus, sputum, and blood can be cultured to grow the organism. Antibodies can be detected in serum of convalescent patients 7–10 days after the onset of disease.

Control of Rats

Rats can be killed by trapping or poisoning them. Rats should be denied three basic requirements essential for their survival, i.e., food, water, and shelter. Food supply of the rats can be reduced

by improving general sanitation, proper disposal of trash and wastes, and properly storing the food meant for human use. Rat burrows can be eliminated by filling them up with a solid material. The burrows can also be fumigated by using calcium cyanide (cyanogas) or carbon-disulfide. Suppression of rodent population during an epidemic should always be associated with anti-flea measures.

Control of Rat-fleas

The insect vector should be eliminated by using an appropriate insecticide. Dichlorodiphenyltrichloroethane (DDT) used to be the insecticide of choice, but of late, several species of flea have become resistant to it. Other commonly used insecticides for flea control include beta-Hexachlorocyclohexane (BHC) and aldrin. The insecticide spray should be carried out both in houses and fields.

Active Immunization

Routine vaccination is not recommended for prevention of plague. The inactivated vaccine, consisting of formalin-killed bacteria, is no longer available. This vaccine had uncertain efficacy in protecting humans, particularly from plague pneumonia, and the long time interval to produce antibodies means that it would be ineffective in the event of a deliberate release of the organism. New sub-unit vaccines are being developed and have much greater efficacy in mice even against plague pneumonia, but have not yet been evaluated for immunogenicity in humans.

Vaccines are not recommended for immediate protection in outbreak situations. Vaccination is only recommended as a prophylactic measure for high-risk groups (e.g., laboratory personnel who are constantly exposed to the risk of contamination). A live attenuated vaccine administered by aerosol is under trial for usage in pneumonic plague.

Health Education

The local community should be educated and trained to eliminate rodents and their breeding places. They should be cautioned against handling dead rats. Maintenance of sanitation and hygiene should be emphasized upon. Factors affecting the transmission and possible preventive strategies should be highlighted.

Surveillance

Plague is a notifiable disease. Periodic surveys should be performed to estimate the extent of infected rats and fleas. Effective control measures should be established well in advance of an outbreak.

IN A NUTSHELL

1. Plague is an infectious disease of rodents which is transmitted to man through the bite of infected ectoparasite (rat-flea) caused by the bacteria *Yersinia pestis*.
2. Plague is transmitted by the bite of insect vectors, the most common being the rat-flea, i.e., *Xenopsylla cheopis*.
3. Humans can acquire plague by (i) bite of an infected flea; or (ii) inhalation of infected droplets from a case of pneumonic plague.
4. *Yersinia pestis* infection has very wide spectrum of clinical presentation, starting from asymptomatic to severe fatal clinical syndrome. Bubonic plague, pneumonic plague, septicemia and meningitis are main clinical presentations of the disease.
5. Streptomycin is the antibiotic of choice for bubonic plague. *S. pneumonic* and septicemic plague may be treated with gentamicin, doxycycline, chloramphenicol or ciprofloxacin.

Chapter 29.16

Brucellosis

Sriram Krishnamurthy

Brucellosis is the most common zoonosis worldwide, and is caused by organisms of the genus *Brucella*. Humans become infected by ingesting animal food products, direct contact with infected animals, or inhaling infectious aerosols (from animal dung or contaminated dust) either by accident or as a result of bioterrorism.

Brucellosis was known to be an occupational disease in animal husbandry and abattoir workers, but is now considered to be primarily a disease associated with the ingestion of unpasteurized milk or dairy products. Clinically, brucellosis is an enigmatic disease. A more often encountered insidious onset of the disease, undulating nature of symptoms, and protean manifestations involving almost any organ system of the body often make the diagnosis difficult. Morbidity in untreated brucellosis is significant. Hence, early diagnosis is important for minimizing untoward outcomes.

Once considered a rare disease in children, it is now known that brucellosis may affect people of all ages, especially in regions where *Brucella melitensis* is the dominant species. The clinical course of illness and the risk of complications appear to be similar irrespective of the age of the patients. The true incidence of human brucellosis is unknown for most countries and no data are available for India. However, the disease may be encountered in significantly numbers in the rural populations of India, who often consume unpasteurized goat's/cow's milk.

EPIDEMIOLOGY

Children could be particularly at risk as they may adopt newborn or sick animals as pets. In some areas they may be the sole group presenting with acute symptoms, as adults are likely to be immune or chronically infected.

The severity and risk of disease are often determined by the type of *Brucella* to which an individual is exposed. *B. melitensis* (associated with sheep and goats) is the type most frequently reported as a cause of human disease and the most frequently isolated from cases. It is the most virulent type and associated with severe acute disease. *B. abortus* (associated with cattle) is the most widespread cause of infection, but associated with much less human disease. *B. suis* (associated with pigs) has a more restricted occurrence than *B. melitensis* and *B. abortus*. It is locally important as a source of human infection which can be as severe as that produced by *B. melitensis*. *B. canis* is a widespread infection of dogs in many countries. It is infrequently associated with human disease. Reported cases have been usually mild.

Although brucellosis in domesticated animals and the consequent transmission of infection to humans has been significantly decreased following the initiation of effective vaccination-based control and prevention programs in various parts of the world, it remains an uncontrolled problem in regions of high endemicity such as the Mediterranean, Middle East, Africa, Latin America and parts of Asia, including India.

Brucellosis is an important but neglected disease in India. Worldwide, the reported incidence of human brucellosis in endemic disease areas varies widely, from <0.01 to >200 per 100,000 population. However, several reports indicate that human brucellosis may be a fairly common disease in India. For example, a study from Bijapur by Mantur *et al* reported on 93 children with brucellosis who were identified by testing blood samples during a period of 13 years. The seroprevalence was 1.6% by serum agglutination test (SAT) (>1:160) and the diagnosis was confirmed in 43 of these pediatric patients by the isolation of *B. melitensis*. During the same period

a total of 492 adult patients were diagnosed with brucellosis at the same hospital indicating the importance of childhood brucellosis. Most of the pediatric patients were shepherds and the habit of consuming fresh goat milk and the close contacts with animals were the most likely risk factors contributing to infection.

ETIOLOGY

Brucellae are nonmotile, nonsporulating, nontoxigenic, non-fermenting, facultative, intracellular, gram-negative small coccobacilli parasites. *Brucella melitensis*, *B. suis*, *B. abortus*, and *B. canis* are the classic causative agents of disease in humans. Cattle, goats, sheep, and pigs are the main reservoirs of *Brucella*. Foodborne transmission is the major source of infection for most populations, with unpasteurized milk and cheese made from raw milk presenting the highest risk. Meat products less frequently lead to infection, since they are not usually eaten raw.

Transmission to humans may also occur through environmental or occupational contact with infected animal tissue and their discharges or from fetuses and placentae; or through direct contact of breaks in the skin and mucous membrane. Infected animals kept in populated areas or passing through close proximity to residential areas may produce heavy contamination of streets, yards or market places, especially if abortions occur in these animals. Inhalation brucellosis may then result from exposure to contaminated dust, dried dung, etc. Certain occupations such as farmers, farm laborers, animal attendants, slaughtermen, butchers, meat packers, dairy workers, shepherds, goatherds, pig keepers, laboratory technicians, veterinarians and inseminators are especially at risk.

Brucellosis may also present as a travel-associated disease. Blood or organ/tissue transfers are also potential sources of infection. Bone marrow transfer in particular carries a significant risk. However, it is known that person-to-person transmission is extremely rare. Occasional cases have been reported in which there was circumstantial evidence to suggest that close personal or sexual contact could be the possible route of transmission.

PATHOGENESIS

The major virulence factor of *Brucella* appears to be its cell wall lipopolysaccharide (LPS). *Brucellae* are intracellular microorganisms that survive and replicate within the reticuloendothelial (monocytes and macrophages) system. *Brucellae* are ingested by the macrophages and localized in the liver, spleen, bone marrow, and lymph nodes. They cause a granuloma formation in these organs. Strains containing smooth LPS are more virulent. Antibodies produced against the LPS antigen provide a means of diagnosis and provide long-term immunity. One of the major factors in recovery from infection is that sensitized T-lymphocytes release cytokines such as IFN- γ and TNF- α , which activate macrophages and increase their intracellular killing capacity.

CLINICAL FEATURES

Human brucellosis usually presents as an acute febrile illness. Most cases are caused by *B. melitensis*. All age groups are affected. It can be very difficult to diagnose in children without a history of food or animal exposure. The signs and symptoms are vague and not pathognomonic. Complications may affect any organ system.

The onset of symptoms may be acute or insidious. It is often a systemic infection characterized by continued, intermittent or irregular fever (often presenting as pyrexia of unknown origin), accompanied by nonspecific systemic symptoms such as headache, vomiting, weakness, sweating, chills, arthralgia, depression, weight loss, pharyngitis, generalized aching, refusal to feed or failure to thrive. Localized infections of organs, including the liver and spleen may be present. Physical findings are few and

include hepatosplenomegaly, arthritis or lymphadenopathy. In fact, most patients demonstrate the clinical triad of fever, arthralgia/arthritis and hepatosplenomegaly. Serious complications include meningitis, endocarditis and osteomyelitis.

COMPLICATIONS

Osteoarticular Complications

Bone and joint involvement are the most common complications of brucellosis, occurring in up to 40% of cases. Monoarticular arthritis of knee and hip in children is common. Sacroiliitis (especially common in adolescents), spondylitis, peripheral arthritis, osteomyelitis, bursitis, and tenosynovitis have been reported. Children often refuse to walk and bear weight on an extremity. Vertebral osteomyelitis has been reported; however paravertebral abscesses are uncommon.

Gastrointestinal Complications

B. melitensis infection is often foodborne, related to consumption of unpasteurized milk or dairy products. Foodborne brucellosis often resembles typhoid fever, since systemic symptoms predominate over gastrointestinal complaints. Still, some patients experience nausea, vomiting, and abdominal discomfort. Rarely ileitis, colitis and spontaneous bacterial peritonitis have been described.

Hepatobiliary Complications

Although the liver is commonly involved in brucellosis, liver function tests are often normal or only mildly elevated. Jaundice is very rare. Disease caused by *B. abortus* may show epithelioid granulomas resembling sarcoidosis. *B. melitensis* infection can cause scattered small foci of inflammation resembling viral hepatitis and rarely, areas of hepatocellular necrosis. Liver abscesses have been described in *B. suis* infections. Postnecrotic cirrhosis is extremely rare.

Pulmonary Complications

A spectrum of pulmonary complications have been described, including hilar or paratracheal lymphadenopathy, interstitial pneumonitis, bronchopneumonia, lung nodules, pleural effusions, and empyema.

Genitourinary Complications

Orchitis and epididymitis are the most common genitourinary complications of brucellosis in males. *Brucella* orchitis is unilateral and can mimic testicular cancer or tuberculosis. Renal involvement is rare. Rare cases of pelvic abscesses and salpingitis have been reported in females.

Cardiovascular Complications

Infective endocarditis is the most common cardiovascular manifestation, and it is reported to be the most common cause of death from brucellosis. Endocarditis is reported in about 2% of cases, and most commonly involves the aortic valve followed by the mitral valve.

Neurological Complications

Neurobrucellosis due to direct invasion of the central nervous system occurs in about 5% of cases of *B. melitensis* infection, leading to meningitis or meningoencephalitis. Headache, mental inattention and depression are common in neurobrucellosis. Other complications include cerebral vasculitis, mycotic aneurysms, brain abscesses, infarcts, hemorrhage, or cerebellar ataxia. Peripheral nerve complications include neuropathy, radiculopathy, Guillain-Barré syndrome, or Poliomyelitis-like syndrome.

Cutaneous Complications

These include rashes, nodules, papules and erythema nodosum. Cutaneous ulcers, abscesses, and suppurative lymphangitis have been reported. Occasionally, cutaneous purpura occur in association with severe thrombocytopenia, which has been ascribed to hypersplenism or hemophagocytic syndrome.

Ophthalmological Complications

Uveitis is the most frequent ophthalmic manifestation and is believed to be immunologically mediated. Steroids are the mainstay of treatment of this complication.

OTHER PRESENTATIONS

Brucellosis may also persist less commonly in the form of *chronic brucellosis* (whose clinical symptoms persist for 12 months or more from the time of the diagnosis); as relapse, chronic localized infection or delayed convalescence. Neonatal and congenital brucellosis has been rarely reported, resulting from transmission through transplacental routes, breastmilk and blood transfusions.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis includes other causes of fever of unknown origin and hepatosplenomegaly such as tuberculosis, malaria, enteric fever, rickettsial fever, leptospirosis, lymphomas, systemic lupus erythematosus and HIV infection. The presence of arthralgia/arthritis with hepatosplenomegaly, along with a history of consumption of unpasteurized milk or milk products, can help arrive at an early diagnosis.

Approach to Diagnosis

As per the case definition for brucellosis, the infection may be diagnosed if any of the following laboratory criteria is met:

- Isolation of *Brucella* from a clinical specimen;
- Four-fold or greater rise in *Brucella* agglutination titer between acute and convalescent phase serum collected greater than 2 weeks apart; and
- Demonstration by immunofluorescence of *Brucella* in a clinical specimen.

A definitive diagnosis can be established by isolating the organism from the blood, bone marrow or other tissues. It is essential to alert the laboratory that brucellosis is suspected, since isolation of the organism may take as long as 4 weeks from blood culture samples, unless lysis centrifugation method is used where results may be available in less than 5 days. The reported frequency of isolation from blood varies from less than 10–90%; *B. melitensis* is said to be more readily cultured than *B. abortus*. Bone marrow cultures are superior in yield as compared to blood cultures.

The tube serum agglutination test (SAT) remains the standard method. It measures the ability of serum to agglutinate killed organisms and reflects the presence of antilipopolysaccharide (LPS) antibody. Usage of the tube SAT test after treating serum with 2-mercaptoethanol to dissociate IgM into monomers helps in detecting IgG antibody; thereby helping in differentiating acute from chronic infections. A titer of 1:160 or higher is considered as diagnostic. To avoid the prozone effect, serum should be used in dilution of more than or equal to 1:320.

The Rose Bengal Test (RBT) is a commonly performed rapid screening test to detect antibodies against LPS, but the results should always be confirmed by other tests detecting agglutinating and nonagglutinating antibody and by culture results, especially in areas where there is a high prevalence of animal brucellosis.

Pancytopenia, anemia, thrombocytopenia or neutropenia may be detected in the peripheral smear in brucellosis, and may provide supportive evidence for diagnosis. Newer methods include

enzyme immunoassay (ELISA), which is however, less sensitive than SAT. Polymerase chain reactions (PCR) are also becoming increasingly available, and could be useful in neurobrucellosis where SAT often is negative.

MANAGEMENT

Brucellae demonstrate in vitro sensitivity to a number of oral antibiotics and to intravenous or intramuscular aminoglycosides. Therapy with a single antimicrobial drug has resulted in a high relapse rate; hence, combined regimens should be used. Nearly all patients also respond to a 6-week oral course with a combination of rifampin and doxycycline combination; fewer than 10% of patients relapse with this regimen. Doxycycline is overall the most effective antimicrobial agent, and when combined with an aminoglycoside, also offers low chance of relapse. Prolonged treatment (for at least 6 weeks) is the key to prevention of relapse.

The optimal treatment for brucellosis in children less than eight years of age has not been conclusively determined. Tetracyclines are contraindicated in this age group because of the potential for permanent staining of deciduous teeth and inhibition of bone growth. β -lactam antibiotics and third generation cephalosporins are not suitable for management of brucellosis since they lack intracellular killing activity, which is essential for eradication of the infection and prevention of relapse.

The recommendations for management of brucellosis in children are summarized in **Box 1**. The onset of therapy may be accompanied by a Jarisch-Herxheimer type of reaction, possibly due to a high antigen load. This may be rarely severe enough to merit steroid therapy.

BOX 1 Treatment of brucellosis

1. For children ≥ 8 years:

First line regimen: Doxycycline (2–4 mg/kg/day; maximum 200 mg/day) orally for 6 weeks PLUS rifampicin (15–20 mg/kg/day; maximum 600–900 mg/day) orally for 6 weeks

Alternative therapy: Doxycycline (2–4 mg/kg/day; maximum 200 mg/day) orally for 6 weeks PLUS streptomycin (15–30 mg/kg/day; maximum 1g/day; IM) for 2 weeks or gentamicin (3–5 mg/kg/day; IM/IV) for 2 weeks

2. For children < 8 years:

Trimethoprim-Sulfamethoxazole (trimethoprim 10 mg/kg/day; sulfamethoxazole 50 mg/kg/day) [maximum dose of trimethoprim 480 mg/day] PLUS rifampicin (15–20 mg/kg/day; maximum 600–900 mg/day) for 6 weeks

3. For children with endocarditis, osteomyelitis and meningitis:

Doxycycline (2–4 mg/kg/day; maximum 200 mg/day) for 4–6 months orally PLUS gentamicin (3–5 mg/kg/day; IV) for 2 weeks PLUS rifampicin (15–20 mg/kg/day; maximum 600–mg/day) orally for 4–6 months

Infected valves in patients with endocarditis may need to be replaced early in therapy.

OUTCOME

Before the advent of specific antimicrobial agents, the course of brucellosis was often prolonged and deaths were known. Since the institution of specific antibiotics, deaths are rare and known to occur in the presence of complications such as neurobrucellosis or endocarditis. Even in these conditions, death rates are low with prolonged antibiotic therapy for 6 months.

PREVENTION

Preventive strategies depend on eradication of the organism from cattle, goats, sheep and pigs. Pasteurization of milk and milk

products is an important aspect of prevention. Consumption of raw unpasteurized milk and milk products from potentially infected cows, goats, and sheep or direct contact with infected animal body fluids or products of conception should be discouraged. Farmers, hunters and animal handlers should be educated about the proper handling of carcasses such as using protective clothing and gloves and when handling potentially infected material and to bury the remains. Safe and effective vaccines for the prevention of human brucellosis are not generally available.

IN A NUTSHELL

1. Human brucellosis usually presents as an acute febrile illness. It affects all ages.
2. Most cases are caused by *B. melitensis*.
3. Complications can affect any organ system. Joint involvement may be seen in up to 40% of cases. Infective endocarditis and neurobrucellosis are rare but serious complications.
4. Brucellosis may persist as relapse, chronic localized infection or delayed convalescence.
5. Cattle, sheep, goats and pigs are the principal reservoirs of *Brucella*.
6. Transmission to humans occurs through occupational or environmental contact with infected animals or their products. Foodborne transmission is the main source of infection, with cheese made from raw milk and unpasteurized milk presenting the highest risk.
7. In acute brucellosis, isolation of *Brucella* from blood, bone marrow or other tissues is confirmatory.
8. Serum agglutination test (SAT) is the most useful serological test, and titres of 1:160 or higher are considered as positive. Culture is often negative, especially in long-standing disease.
9. The essential principle in the management of all forms of human brucellosis is the administration of effective antimicrobial agents for an extended period of time.
10. For children more than 8 years of age, doxycycline plus rifampicin for 6 weeks is the first line regimen, while for children less than 8 years of age, trimethoprim-sulfamethoxazole with rifampicin for at least 6 weeks is the treatment of choice.

Chapter 29.17

Relapsing Fever

P Ramachandran

Relapsing fever is a zoonotic arthropod-borne infection caused by the spirochetes of *Borrelia* species characterized by recurrent cycles of pyrexia which are separated by intervals of apparent recovery. Based on the vector responsible, it can be tick-borne relapsing fever (TBRF) or louse-borne relapsing fever (LBRF). TBRF is reported all over the world though only sporadic cases are reported from India. Outbreak of LBRF occurs in the refugee camps of war and famine affected African countries. There is a paucity of information about relapsing fever in India.

EPIDEMIOLOGY

Tick-borne relapsing fever is found in discrete areas throughout the world, including mountainous areas of North America, plateau regions of Mexico, Central and South America, the Mediterranean, Central Asia, and much of Africa. LBRF causes sporadic illness and outbreaks in sub-Saharan Africa, particularly in regions affected by war and in refugee camps. LBRF is commonly found in Ethiopia, Sudan, Eritrea, and Somalia. Illness can be severe, with mortality rate of 30–70% in outbreaks.

ETIOLOGY

Relapsing fever is caused by spirochetes of *Borrelia* species and transmitted by arthropods (ticks or lice). TBRF is caused by many species of *Borrelia* while LBRF is caused by only *Borrelia recurrentis*. In North India, TBRF is spread by *Ornithodoros tholozani*, *Ornithodoros crossi*, *Ornithodoros lahorensis* and the fowl tick *Argas persicus*. TBRF is a zoonosis and is enzootic in many countries. It is spread by multiple tick species, each of which has a preferred habitat and set of hosts. *Borrelia* that cause TBRF are transmitted to humans through the bite of infected *soft ticks* of the genus *Ornithodoros*. They live within rodent burrows, feeding as needed on the rodent as it sleeps. Humans typically come into contact with soft ticks when they sleep in rodent-infested cabins mostly in summer months while vacationing. Rodents and other animals serve as natural reservoirs. TBRF is acquired directly through the tick bite, usually from saliva secreted by the tick into the skin.

Louse-borne relapsing fever is principally a disease seen in the developing world; it is spread from person to person by the body louse *Pediculus humanus corporis*, which only feeds on humans and lives on clothing. Humans are probably the only reservoir of *B. recurrentis*. LBRF can occur in epidemics, including large ones involving millions of people generally in refugee settings. LBRF outbreaks most commonly occur in conditions of overcrowding and social disruption. LBRF is acquired when people crush a louse with their fingers; the organism is introduced at the bite-site, into the skin of the crushing fingers, or into the conjunctivae when they rub their eyes.

PATHOGENESIS

Spirochetes causing relapsing fever have a unique process of DNA rearrangement that allows them to periodically change the molecules on their outer surface. This process, called antigenic variation, allows the spirochete to evade the host immune system and causes relapsing episodes of fever and other symptoms. These variable proteins determine differences in disease expression. For example, propensity for invasion of the central nervous system with *Borrelia turicatae* infection is determined by variability in a single surface protein of the bacterium.

CLINICAL FEATURES

The incubation period for clinical illness from the bite is 5–10 days. Relapsing fever is characterized by episodes of sudden onset of high fever which may be as high as 43°C and is usually above 39°C lasting for 2–9 days, followed by afebrile periods of about 7 days, followed by another episode of fever (**Fig. 1**). This process can recur from 3 to 10 times. Duration of fever during febrile phase is shorter in TBRF compared LBRF. Along with fever, patients may experience generalized bodyache, muscle pain, joint pain, headache, nausea, vomiting, anorexia, dry cough, rash, neck pain, eye pain, confusion and dizziness (**Table 1**). During the end of the primary febrile episode, a diffuse, erythematous, macular, or petechial rash lasting up to 2 days can develop over the trunk and shoulders.

Each febrile episode ends with a *crisis*. During the *chill phase* of the crisis, patients develop very high fever (up to 106.7°F or 41.5°C) with rigors and may become delirious, agitated, hypertensive, and develop tachycardia and tachypnea lasting for 10–30 min. This phase is followed by the *flush phase*, characterized by drenching sweats and a rapid decrease in body temperature and transient hypotension. This phase usually persists for several hours. Overall, patients who are not treated will experience recurrent episodes of fever before illness resolves. On physical examination, there are no findings specific for TBRF. Patients typically appear moderately ill and may be dehydrated. Splenomegaly, which the patient can experience as abdominal or left shoulder pain, and hepatomegaly can occur in both LBRF and TBRF. Less frequently, patients may have jaundice, meningismus, and photophobia (**Table 1**).

Acute respiratory distress syndrome may occur in TBRF. Localizing neurologic symptoms, including hemiplegia, facial palsy, myelitis, and radiculopathy are more common in TBRF. Epistaxis, petechiae, and ecchymoses are common in LBRF.

Tick bite

Figure 1 Timeline of relapsing fever

Table 1 Symptoms and signs among patients with tick-borne relapsing fever

Symptom	Frequency of symptom	Sign	Frequency of sign
Headache	94%	Confusion	38%
Myalgia	92%	Rash	18%
Chills	88%	Jaundice	10%
Nausea	76%	Hepatomegaly	10%
Arthralgia	73%	Splenomegaly	6%
Vomiting	71%	Conjunctival injection	5%
Abdominal pain	44%	Eschar	2%
Dry cough	27%	Meningitis	2%
Eye pain	26%	Nuchal rigidity	2%
Diarrhea	25%		
Photophobia	25%		
Neck pain	24%		

Source: Centers for Disease Control, Atlanta, USA

Myocarditis can occur in both LBRF and TBRF. Delirium or apathy and occasionally stupor or coma also can occur in both forms.

Malaria, influenza, typhoid fever, brucellosis, rickettsioses, dengue, leptospirosis, rat-bite fever, meningococcemia and viral hepatitis should be considered in the differential diagnosis.

Mortality from untreated relapsing fever is most common during the crisis and its immediate aftermath and is usually associated with myocarditis, hepatic failure or disseminated intravascular coagulation.

LABORATORY DIAGNOSIS

The definitive diagnosis of TBRF is based on the observation of *Borrelia* spirochetes in peripheral blood, bone marrow, or cerebrospinal fluid in a symptomatic person (Fig. 2). It is best visualized by dark field microscopy of peripheral blood, but can also be detected in thin smear or thick smear using Wright-Giemsa or acridine orange stains. The organisms are best detected in blood obtained while a person is febrile. With subsequent febrile episodes, the number of circulating spirochetes decreases, making it harder to detect. Even during the initial episode spirochetes will only be seen 70% of the time.

Blood samples obtained before antibiotic treatment can be cultured using Barbour-Stoner-Kelly (BSK) medium or by inoculating immature mice. The spirochete will usually be evident within 24 hours if the blood was drawn during a febrile episode. The polymerase chain reaction (PCR) is useful for identifying the infecting species. These are done only in reference labs.

Serologic testing is not useful for immediate diagnosis. To confirm the diagnosis of TBRF, *Borrelia* specific antibody titers should increase 4-fold between acute and convalescent serum samples. The rise in antibody titer may be blunted by early antibiotic therapy. Serologic testing for TBRF is not standardized and results vary by laboratory.

Nonspecific laboratory findings include normal to increased white blood cell count with a left shift, a mildly increased serum bilirubin level, mild to moderate thrombocytopenia, elevated erythrocyte sedimentation rate (ESR), and slightly prolonged prothrombin time (PT) and partial thromboplastin time (PTT). The electrocardiogram may reveal a prolonged QTc interval in patients with myocarditis. Some such patients have cardiomegaly and pulmonary edema on chest radiograph. Analysis of the

Figure 2 Photomicrograph revealing the presence of numerous *Borrelia recurrentis* bacteria, which cause European relapsing fever. This bacterium is transmitted from person-to-person by way of the human body louse, *Pediculus humanus* var. *corporis*.

Source: PHIL, Centers for Disease Control, Atlanta, USA.

cerebrospinal fluid (CSF) is indicated when there are signs of meningitis or meningoencephalitis. The presence of pleocytosis and/or mildly to moderately elevated protein levels in the CSF requires intravenous antibiotic therapy.

TREATMENT

Tick-borne relapsing fever spirochetes are susceptible to penicillin and other beta-lactam antimicrobials, as well as tetracyclines and macrolides. Oral or parenteral tetracycline is the drug of choice for LBRF and TBRF. In TBRF for children above 8 years of age and young adults, tetracycline 500 mg or 12.5 mg/kg PO every 6 hours or doxycycline 100 mg or 2.5 mg/kg PO every 12 hours for 10 days is effective. For children below or equal to 8 years of age erythromycin 12.5 mg/kg every 6 hours for 10 days is effective.

In contrast to TBRF, LBRF caused by *B. recurrentis* can be treated effectively with a single dose of antibiotics. Doses for children are oral tetracycline at 12.5 mg/kg, oral doxycycline at 5 mg/kg, and intramuscular penicillin G procaine at 200,000–400,000 units. For children above 8 years of age and adults, a single dose of oral tetracycline 500 mg, oral doxycycline 200 mg or intramuscular penicillin G procaine 400,000–800,000 units is effective. Alternative is oral erythromycin, 500 mg for adults and 12.5 mg/kg for children. Intravenous penicillin G or ceftriaxone for 10–14 days is effective treatment for CNS involvement.

When initiating antibiotic therapy, all patients should be observed during the first 4 hours of treatment for a Jarisch-Herxheimer reaction. The reaction, a worsening of symptoms with rigors, hypotension, and high fever, occurs in over 50% of cases and may be difficult to distinguish from a febrile crisis. Supportive care is required for the symptoms. Features associated with a poor prognosis are, stupor or coma on admission, diffuse bleeding, myocarditis, poor hepatic function, bronchopneumonia, coinfection with typhus, typhoid or malaria. In addition acute respiratory distress syndrome requiring ventilatory support has been described in TBRF.

COMPLICATIONS AND PROGNOSIS

Given appropriate treatment, most patients recover within a few days. The mortality rates for untreated LBRF and TBRF are in the ranges of 10–70% and 4–10%, respectively. With prompt treatment with appropriate antibiotics, the death rate for LBRF is 2–5% and for TBRF is less than 2%. Long-term sequelae of TBRF are rare but include iritis, uveitis, cranial nerve involvement, and other neuropathies.

TICK-BORNE RELAPSING FEVER IN PREGNANCY

Tick-borne relapsing fever contracted during pregnancy can cause spontaneous abortion, premature birth, low-birthweight and neonatal death. The maternal-fetal transmission of *Borrelia* is believed to occur either transplacentally or while traversing the birth canal. In general, pregnant women have higher spirochete loads and more severe symptoms than nonpregnant women.

PREVENTION

The risk for tick-borne disease can be minimized in endemic areas by maintaining rodent-free dwellings. Ticks can be destroyed by spraying with lindane 1% (gamma benzene hexachloride). Visitors to infected areas should wear protective clothing and use insect repellants. Ticks should be looked for and removed mechanically from the body before going to bed after the day's work. Giving prophylactic doxycycline for 4 days after a tick bite has been shown to prevent TBRF. LBRF can be prevented by lowering the risk of louse infestation through improved personal hygiene, reduction of crowding and better access to washing facilities.

IN A NUTSHELL

1. Relapsing fever is a zoonotic arthropod-borne infection caused by the spirochetes of *Borrelia* species.
2. The two major forms of the disease are tick-borne relapsing fever (TBRF) or louse-borne relapsing fever (LBRF).
3. TBRF is seen throughout the world while LBRF is seen mainly in Sub-Saharan Africa. Sporadic cases of TBRF are reported in India.
4. Relapsing fever is characterized by episodes of high-grade fever with other constitutional symptoms followed by afebrile periods and this cycle recurs for 3–10 times.
5. Spirochetes causing relapsing fever periodically change the molecules on their outer surface and this antigenic variation allows the spirochete to evade the host immune system and causes relapsing episodes.
6. The other characteristic of the febrile episodes are that they end with a *chill phase* of 10–30 minutes of high fever, rigors, tachycardia and tachypnea and a *flush phase* of several hours characterized by marked sweating, sudden decrease in temperature and transient hypotension.
7. Fatal complications, such as myocarditis, acute liver failure, ARDS, DIC and meningoencephalitis, can occur in untreated cases.
8. Diagnosis depends on demonstration of spirochetes by dark-field microscopy or in thin or thick blood smears stained with Giemsa or Wright's stain.
9. For TBRF in children above 8 years of age and adults, tetracycline or doxycycline for 10 days is the preferred treatment. For children below or equal to 8 years of age erythromycin for 10 days is the preferred regimen. For LBRF these drugs are given as a single dose. For neurologic complications intravenous penicillin or ceftriaxone is indicated.
10. Mortality is high in untreated cases especially LBRF.

Chapter 29.18

Lyme Disease

P Ramachandran

Lyme disease derives its name from the town *Lyme* in Connecticut, America, where it was first recognized in 1977. Lyme disease is focally endemic in temperate zones of North America, Europe and Asia. Sporadic cases are reported in India with skin, eye and neurologic manifestations. It is a tick-borne spirochetal infection.

ETIOLOGY

The members of *Borrelia* species are spirochetes, which are motile, spiral, or wavy bacteria. Infection occurs through the bite of infected ticks, both adults and nymphs, of the genus *Ixodes*. Three species of *Borrelia* account for most cases of Lyme disease in the world: *Borrelia burgdorferi* causes Lyme disease in North America and less extensively in Europe. In Europe and Asia, *Borrelia afzelii* and *Borrelia garinii* are the predominant species. In Asia, *B. afzelii* and *B. garinii* are thought to be the most common causes of Lyme disease. However, *B. burgdorferi* has also been detected from a skin lesion of a patient with Lyme disease in Taiwan. Biological differences among the three predominant *Borrelia* species are likely to be responsible for some of the differences in clinical manifestations. The lifecycle of *B. burgdorferi* requires a tick host and a mammalian host. *B. afzelii* is mainly associated with rodents as reservoirs, whereas *B. garinii* is mainly associated with birds as reservoir.

PATHOGENESIS

B. burgdorferi is deposited in skin during tick feeding. After inoculation into the skin, *Borrelia* begins to multiply rapidly. *Borrelia* species do not produce potent toxins, but cause illness by migrating through tissues, disseminating in the blood, adhering to host cells, and producing immunologic response. Dissemination to distant sites begins to occur within two to three days. The spirochete adheres to the surfaces of a wide variety of different types of cells, but the principal target organs are skin, central and peripheral nervous system, joints, heart, and eyes. The symptoms of disseminated Lyme disease are due to inflammation mediated by interleukin 1 and other lymphokines in response to the presence of the organisms. During untreated late stage infection in mammals, symptoms persist at specific sites like joints, central nervous system (CNS) and it is suspected that *B. burgdorferi* may persist at low levels in these tissues.

CLINICAL FEATURES

There are three stages of Lyme disease:

Early Localized Disease (Stage 1)

Clinical features are similar to flu such as fever, headache, tiredness, neck pain, arthralgia or myalgia. A flat or slightly raised red spot called erythema migrans (EM) appears at the site of the tick bite with a clear area in the center (bull's eye rash) (**Fig. 1**). Without treatment, it can last 4 weeks or more (**Table 1**). It is usually a painless rash that appears within 7–14 days after the bite (range 3–30 days). The absence of a recognized tick bite does not exclude Lyme disease, as long as exposure to tick bite in an endemic area is a possibility. Untreated, the rash expands over the course of days to weeks to form a large, annular, erythematous lesion that is at least 5 cm and as much as 70 cm in diameter (median 15 cm). The lesions are seen commonly over the head and neck in younger children

and arms and lower limbs in older children. It may also be seen over back and other areas. Though a central clearing of rash is mentioned as a typical feature, in most cases it is uniformly erythematous.

Early Disseminated Disease (Stage 2) (Table 1)

Multiple erythema migrans, cranial nerve palsy, meningitis and carditis are the clinical manifestation of this stage which may occur days to weeks after the tick bite. *Multiple erythema migrans* is a pathognomonic feature in endemic areas. Cranial nerve palsy usually involves facial nerve as unilateral or sometimes bilateral facial palsy. Meningitis is manifested by headache, nuchal rigidity and papilledema. Lyme meningitis in children is frequently associated with increased intra cranial pressure which may lead to transient or permanent loss of vision. Carditis manifests with I or II degree or complete heart block, rarely with myocarditis or left ventricular dysfunction. Systemic signs and symptoms, such as fever, fatigue, headache, and arthralgia are common in this stage of Lyme disease.

Late Disease (Stage 3)

Late disease presents weeks or months after primary infection if not treated adequately. Arthritis is the most common manifestation of late Lyme disease (**Table 1**). There is a wide variability in the severity of Lyme arthritis. The arthritis is usually monoarticular or oligoarticular and affects the large joints, particularly the knee, which is involved in more than 90% of cases. Many present with migratory

Figure 1 Erythema migrans with central clearing (bull's eye)
(Courtesy: James Gathany, PHIL, CDC, USA)

Table 1 Clinical stages of Lyme disease

Stage	Duration after tick bite	Clinical features
Stage 1	3–30 days	Erythema migrans (single), variable constitutional symptoms (headache, fever, myalgia, arthralgia, fatigue)
Stage 2	4–12 weeks	Multiple erythema migrans, cranial neuritis (commonly facial nerve), meningitis, papilledema, carditis (heart block), ocular disease; constitutional symptoms common
Stage 3	Above 8 weeks	Mono or oligoarthritis mainly involving knee; resolve and recur to involve multiple joints

arthritis. In some instances it may be confused with acute bacterial arthritis. The differentiating features are, children with Lyme arthritis can bear weight and walk and fever is not an associated feature. The arthritis may slowly resolve and may recur to involve multiple joints. Long-term prognosis of Lyme arthritis in children is excellent.

DIAGNOSIS

The diagnosis of early Lyme disease should be made on clinical grounds alone when a characteristic EM lesion is present in a patient who lives in or has recently traveled to an endemic area. EM initially can be confused with nummular eczema, tinea corporis or granuloma annulare. The relatively rapid expansion of EM helps to distinguish it from these other skin lesions. The clinical manifestation of arthritis of late stage is sometimes confused with a septic arthritis or other causes of arthritis in children, such as juvenile rheumatoid arthritis or rheumatic fever. The facial nerve palsy due to Lyme disease is clinically indistinguishable from idiopathic Bell's palsy, although bilateral involvement is much more common with Lyme disease.

Immunoglobulin (Ig) M antibodies to *B. burgdorferi* typically appear in 3–4 weeks. IgG antibodies appear in 4–8 weeks and peak at 4–6 months. Serology is likely to be negative in early localized stage (stage 1). In early disseminated Lyme disease (stage 2) serologic tests are usually positive for both IgM and IgG antibodies. In late disease (Lyme arthritis), serologic tests should be positive for IgG antibodies. Both IgM and IgG antibodies may remain elevated despite successful antibiotic therapy and complete resolution of symptoms.

When serologic testing is indicated, a two-tier testing is recommended. Initially an enzyme-linked immunosorbent assay (ELISA) followed by a Western blot are the tests of choice. This two-tier testing is recommended because of its high degree of sensitivity and specificity compared to a single test. Polymerase chain reaction (PCR) test has some usefulness when done in synovial fluid in arthritis cases, but not useful in cerebrospinal fluid due to high false positivity.

TREATMENT

The goal of therapy is to shorten the duration of the early disease and to reduce the risk of development of late Lyme disease. *B. burgdorferi* is highly susceptible to beta-lactam antibiotics and tetracyclines. They are of equivalent choice for treatment for early Lyme disease, doxycycline for above 8 years and amoxicillin for less than 8 years of age. Of the oral agents, doxycycline has the best penetration into the CNS. Doxycycline is not recommended for children under the age of 8 years or for pregnant or lactating women. However, a single treatment course of doxycycline may be given to children younger than 8 years in whom the alternate agents are contraindicated. The doses and duration are listed in **Box 1**.

BOX 1 Recommended treatment of Lyme disease

Drug and doses

1. Amoxicillin 50 mg/kg/day PO in 3 divided doses
2. Doxycycline 4 mg/kg/day PO in 2 divided doses
3. Cefuroxime 30 mg/kg/day PO in 2 divided doses (max 1,000 mg/day)
4. Ceftriaxone 50–75 mg/kg/day IV OD

Duration of therapy: 2–3 weeks for cardiac disease, erythema migrans, and cranial neuritis; up to 4 weeks for meningitis and arthritis. Carditis and meningitis should preferably be treated with injectable drugs.

Response to Therapy

Majority of patients with early Lyme disease who receive appropriate antibiotic therapy have complete resolution of the signs and symptoms of infection within 20 days. Patients who have systemic illness at the beginning of treatment may take longer to recover. In addition, appropriate dosing and duration of therapy early in the course (i.e., within weeks of the onset of infection) prevents progression to late Lyme disease. Infectious Diseases Society of America (IDSA) guidelines 2006 recommend parenteral therapy with ceftriaxone when abnormal CSF findings are present (**Box 1**). Patients with isolated facial nerve palsy in the absence of meningitis are treated with oral doxycycline.

PREVENTION

Personal protection against tick bites is useful by application of tick repellents, such as diethyl-3-methylbenzamide (DEET), on skin and permethrin on clothing. Promptly removing ticks after exposure to tick habitat also will reduce the infection risk to some extent.

IN A NUTSHELL

1. Lyme disease (Lyme borreliosis) is a spirochetal infection caused by *Borrelia* species and transmitted by tick. Borreliosis involving eye, skin and nervous system have been reported from India.
2. The hall mark of early localized disease is erythema migrans. This stage lasts for about 4 weeks.
3. Early disseminated disease (the second stage) starts after about 4 weeks of tick bite. It is characterized by multiple erythema migrans, cranial neuritis (facial palsy-unilateral or bilateral), myocarditis, and eye involvement. This stage lasts up to 3 months.
4. In the third stage (late disease) arthritis is the hall mark. It starts after about 2 months of onset with mono/oligoarthritis and later recur involving multiple joints. Complete resolution occurs.
5. The diagnosis of early localized disease is only clinical with the presence of erythema migrans and antibodies are usually not present in this stage. IgM and IgG antibodies are present in the second stage while IgG antibodies are seen in the third stage.
6. Beta-lactam antibiotics like amoxicillin are given for children equal to or below 8 years of age, while doxycycline is preferred for children above 8 years of age. For CNS involvement intravenous ceftriaxone is the drug of choice.

Chapter 29.19

Nocardiosis

Subhasish Bhattacharyya

Nocardiae are found in environment, notably in soil and over 30 species have been showed to be associated with opportunistic disease in human, termed as Nocardiosis, which includes acute, sub-acute or chronic suppurative infections with a tendency for remission and exacerbations. Principal causes of the disease are *Nocardia asteroides* (including *Nocardia cyriacigeorgica*) so named because of their star-shaped colonies. Other causes of the disease are *Nocardia farcinica*, *Nocardia brasiliensis*, *Nocardia abscessus*, *Nocardia otitidiscaviarum*, *Nocardia nova* and *Nocardia transvalensis*. *N. brasiliensis* infections are often limited to skin and subcutaneous tissue and all other species have been reported in pulmonary and systemic infections.

MICROBIOLOGY

The family *Nocardiaceae* is composed of aerobic actinomycetes and characterized by filamentous growth with true branching, are catalase and urease positive and grow on multiple media including Lowenstein-Jensen medium, brain-heart infusion agar, simple blood agar and sabouraud dextrose agar. They grow best at 37°C in presence of 10% carbon-dioxide. It takes 2–4 weeks to recognize the morphologic characteristics of the colony. Laboratory personnel should be notified to observe this culture for at least 4 weeks, when nocardiosis is considered. Many *Nocardia* are acid fast, so a modified Ziehl-Neelsen or Kinyoun stain with 1% sulfuric acid decolorization is best for demonstrating *Nocardia*. *Nocardia asteroides* is the most common and *N. brasiliensis* is the second most frequent etiologic agent of human nocardiasis.

EPIDEMIOLOGY

Nocardia are ubiquitous saprophytic soil organism usually found in house dust, garden soil, fresh water, decaying vegetation and swimming pools. The lung is the primary portal of entry of nocardiosis. Nearly all cases are sporadic, but outbreaks have been associated with contamination of hospital environment, solutions or drug injection equipment. Person to person spread is rare, there is no seasonality, risk of pulmonary and disseminated disease is greater than usual among the people with deficient cell-mediated immunity, lymphoma, lymphoreticular malignancy, Chronic obstructive pulmonary disease (COPD), transplantation, AIDS (< 250 CD4 + T-lymphocytes/ μ L), glucocorticoid therapy. Incidence increases up to 140 folds greater among the patients with AIDS and nearly 340 folds greater among the bone marrow recipient than the general population. It is also associated with tuberculosis, chronic granulomatous disease and treatment with monoclonal antibodies to tumor necrosis factor (infliximab). Any child with nocardiosis and known cause of immunosuppression should undergo tests to determine adequacy of the phagocytic respiratory burst. This infection mostly occurs in tropical and subtropical regions especially in Southeast Asia and India, and the most important risk factor is frequent contact with soil or vegetable matter.

PATHOGENESIS

Infection usually occurs by inhalation of bacilli or occasionally by traumatic inoculation into the skin following arthropod and cat bites. Characteristic histologic feature of nocardiosis is an abscess with extensive neutrophil infiltration and prominent necrosis

without extensive fibrosis, granulomatous inflammation or encapsulation. It survives within the phagocytes by neutralization of oxidants, prevention of phagosome lysosome fusion and prevention of phagosome acidification. Neutrophil do not kill them efficiently. Nocardiosis produces suppurative necrosis and abscess formation similar to that seen in pyogenic infection. Disseminated infection occurs via hematogenous spread, especially in immunocompromised host. Keratitis, either post traumatic or associated with contact lens use and endophthalmitis have been reported.

CLINICAL MANIFESTATIONS

Pulmonary nocardiosis, the most common form of nocardial disease in the respiratory tract occurring in more than two-third cases, causes acute, subacute or chronic suppurative disease. Pulmonary infection can manifest with dyspnea along with anorexia and weight loss. Cough is prominent and produces thick, purulent nonmalodorous sputum, hemoptysis is rare. Chronic pulmonary nocardiosis is much like tuberculosis. Widespread dissemination can occur specially in solid-organ transplant recipients and immunocompromised hosts.

Central nervous system is most common secondary site, where disease manifest as single or multiple brain abscesses, usually supratentorial and often multiloculated. *N. farcinica* and *N. otitidiscaviarum* mostly associated with brain abscess which may have implications for treatment due to their antibiotic resistance pattern. *Nocardia* also has been associated with persistence neutrophilic meningitis, despite negative routine culture. Neurotropism is so prominent a feature of nocardiosis that cranial CT and MRI imaging should be performed in patients with pulmonary infection even without symptoms of CNS disease. Imaging typically shows a necrotic cavity surrounded by contrast-enhancing smooth capsule of uniform thickness and surrounding edema, in contrast to more irregular capsule seen in malignant tumors. MRI T₂—weighted image may show multiple concentric rings with varying signal intensities.

Skin manifestations (third most commonly involved organ) include cellulitis, pustules, pyoderma, ulcerations, subcutaneous abscess and mycetoma. Patient with skin involvement should be evaluated to exclude disseminated disease. *Nocardia* can disseminate to almost any organ like kidney (fourth most common site), intestine, liver, spleen, joints, bones and adrenal glands. Renal manifestations are dysuria, hematuria and pyuria.

DIAGNOSIS

Sputum or pus examination shows crooked, branching, beaded, gram-positive weak acid-fast filaments (by modified Kinyoun, Ziehl-Neelsen method). *Nocardiae* grow relatively slowly; develop characteristic appearance till 4 weeks. Laboratory should be alerted when nocardiosis is suspected in order to maximize the isolation.

TREATMENT

Sulfonamides are the drug of choice for nocardiosis. The combination of sulfamethoxazole (SMX) and trimethoprim (TMP) is probably equivalent to sulfonamides that may be more effective. At the outset, 10–20 mg/kg of TMP and 50–100 mg/kg of SMX should be given each day in two divided doses and later daily dose can be decreased. Importantly, thrice weekly TMP-SMX used for *Pneumocystis jirovecii* infection prophylaxis, is ineffective in preventing nocardiosis. Duration of the treatment varies from 6–12 months depending upon the clinical manifestations and host defenses. TMP-SMX resistance range from 20% for *N. brasiliensis* to 80% for *N. farcinica*. Linezolid is the only antibiotic to which 100% of the isolates are susceptible. Resistance among all stains tested is

lowest for amikacin (5%), which is best established parenteral drug and is given in a dose of 5–7.5 mg/kg every 12 hourly. TMP-SMX with amikacin combination should be used for progressive disease especially in immunocompromised host. Mortality ranges from 15% to 26%; the factor that increases mortality includes concurrent corticosteroid or antineoplastic therapy and cytomegalovirus coinfection. Consideration of nocardial infection in a differential diagnosis of immunocompromised or debilitated patient should be considered for earlier diagnosis and improved outcome. Despite appropriate therapy, the overall mortality rate is more than 50%, may be due to delayed diagnosis.

Jacobs RF, Schutze GE. *Nocardia*. In: Kliegman RN, Behrman RE, Jenson HB, Stanton BF. Nelson Textbook of Pediatrics. 18th ed. Philadelphia: Saunders, Elsevier; 2007. pp. 1162-3.

IN A NUTSHELL

1. *Nocardia* is a ubiquitous soil organism.
2. Most infections occur in children with HIV infection and immunodeficiency, chronic high dose corticosteroid therapy, lymphoreticular malignancies, organ transplantations.
3. Pulmonary disease occurs in more than two-third of cases; disseminated disease involves CNS and any other organ.
4. Cutaneous and lymphocutaneous nocardiosis are due to direct inoculation.
5. Laboratory personnel should be notified to hold the culture at least for 2 weeks to allow the slow growth of *Nocardia*.
6. TMP-SMX is the treatment of choice. Other agents include linezolid, amikacin and ceftriaxone. Duration of therapy for invasive disease is 6–12 months or more.

Chapter 29.20

Actinomycosis

Subhasish Bhattacharyya

Actinomycosis is a slowly progressive infection caused by anaerobic or microaerophilic filamentous, branching, gram-positive, nonspore forming, catalase-negative bacilli. It is a chronic granulomatous, suppurative disease, characterized by extension to contiguous tissue with the formation of numerous draining fistulas and sinuses. On Gram stain, *Actinomyces* cannot be distinguished from *Nocardia*, which grows aerobically and stain with modified acid-fast technique but *Actinomyces* species do not. *Actinomyces Israelii* is the predominant species causing disease. Most infections are polymicrobial, involving other anaerobic and aerobic bacteria. Comparative 16S rRNA gene sequencing has led to the identification of expanding list of *Actinomyces* spp.

EPIDEMIOLOGY

Actinomyces has no geographical boundaries. Mucosal disruption may lead to infection at virtually any site of the body. Actinomycosis has been called most misdiagnosed disease, is often missed by experienced clinicians. *Actinomyces* species colonize the oral cavity (carious teeth, dental plaque and tonsillar crypts) prevalence rate increasing from 31% to 97% within the first two years of life.

PATHOGENESIS

Actinomyces species generally have low virulence. A critical step in the development of Actinomycosis is disruption of mucosal barrier, infection (herpes simplex, cytomegalovirus infection), trauma, and surgical injury of mucous membrane. Pulmonary infections usually follow aspiration of secretions. Once established it spreads continuously in a slow progressive manner, ignoring tissue planes, producing characteristic chronic, indolent single or multiple indurations with central necrosis consisting of neutrophils and sulfur granules with fibrotic wall. Over time, sinus tracks to skin and adjacent organs to bone may develop. Some features of this disease may mimic malignancy. Immunodeficiency, HIV infection, radio- or chemotherapy and transplantation facilitate the development of actinomycosis. Patient with chronic granulomatous disease have an unusual susceptibility to *Actinomyces* infection.

CLINICAL MANIFESTATIONS

Actinomyces occur most frequently at an oral, cervical or facial site (generally at the angle of the jaw, "lumpy jaw") often mistaken for neoplasm. Classically, small abscess form at the site of origin, with an extension to form multiple sinus tracks that can drain yellow, gritty, purulent material (sulfur granules). Contagious extension to the cranium, cervical spine, or thorax is potential sequelae. Fever or systemic illness is usually absent. Appendix is the most frequent gastrointestinal site and appendicitis with perforation is the most common predisposing event. Chronic nonspecific symptoms consisting of fever, chills, weight loss, diarrhea, constipation, abdominal pain may present and mimic tuberculosis or lymphoreticular malignancy. It must be differentiated from tuberculosis, nocardiosis and fungal infection. Sinus tracts to the abdominal wall, to the perianal region or between the bowel and other organs may develop and mimic inflammatory bowel disease. Thoracic actinomycosis presents with chronic indolent and slowly progressing pneumonia with or without plural involvement, also may mimic tuberculosis, lung abscess and nocardiosis.

DIAGNOSIS

Diagnosis of Actinomycosis is rarely considered. Gram and acid-fast stain are helpful in differentiating probable *Actinomyces* from aspirations and biopsies. Aspirations and biopsies (with or without CT or ultra sound guidance) are being used successfully to obtain clinical material for diagnosis, although sometimes surgery may be required. Isolation of the organism is extremely important to confirm the disease. For microbiologic identification, the avoidance of even a single dose of antibiotic is mandatory before isolation, which usually requires 5–7 days, but may take as long as 2–4 weeks. Sometimes a less fastidious co-pathogen, *Aggregatibacter actinomycetemcomitans* is a sole isolate and predicts the presence of *Actinomyces*.

TREATMENT

Actinomycosis requires prolonged treatment (6–12 months) with high dose of anti microbial agents. Usually cervicofacial infection responds to antibiotic alone but surgical drainage and excision may be required for large thoracic, abdominal and soft-tissue abscesses. *Actinomyces* are exquisitely susceptible to penicillin, extended-spectrum penicillin and wide range of β -lactam agents with or without combination of β -lactamase inhibiting agents. However, metronidazole is ineffective. Initially, aqueous penicillin G (2,50,000 U/kg/day) in four divided doses should be used intravenously for 2–6 weeks followed by 6–12 months of amoxicillin or oral penicillin. Latest evidences support an initial attempt at cure with medical therapy alone even in extensive disease. CT and MRI should be used to monitor the response to therapy. The prognosis is excellent with early diagnosis and surgical debridement and antimicrobial therapy. Treatment of periodontitis or caries may eliminate source of possible reinfection.

IN A NUTSHELL

1. *Actinomyces israelii* is a filamentous, branching, gram-positive, catalase-negative and anaerobic bacillus.
2. It is a normal flora of mouth, GI tract and female genital tract; and attains access to tissue via mucosal breach, trauma or by aspiration.
3. Special hosts at risk are immunocompromised patients, AIDS and those with chronic granulomatous disease.
4. Actinomycosis is a chronic granulomatous, suppurative disease, characterized by extension to contiguous tissue with the formation of numerous draining fistulas and sinuses. Most common sites of infection are face, neck, abdomen and pelvis.
5. On Gram stain, *Actinomyces* cannot be distinguished from *Nocardia*.
6. Prolonged antimicrobial therapy with penicillin or cephalosporins is the key to treatment.

Chapter 29.21

Helicobacter pylori

John Matthai, Sarah Paul

Helicobacter pylori is a highly motile, slow-growing, Gram-negative spiral organism with the unique ability to produce large amounts of the urease enzyme. This enzyme is the key to colonization of the gastric mucosa. It is also the basis of rapid urease test (RUT) and the urea breath test which are indirect markers of the presence of the organism. *H. pylori* has a special affinity for the gastric mucosa and is etiologically linked to chronic active gastritis, peptic ulcer and gastric cancer in adults. However, this association is less well-established in children. In developing countries the infection is usually acquired in early childhood and persists throughout life unless a specific treatment is given. The chronic gastric inflammation which it induces, is asymptomatic in children, but may be a precursor for peptic ulcer disease and gastric malignancies in adulthood.

EPIDEMIOLOGY

Over the last two decades, the prevalence of *H. pylori* in the younger generation has declined in developed countries. However, the prevalence is still high in developing countries with lower socioeconomic status overcrowding and unhealthy living conditions. Studies in India show that more than 50% of children are infected by 10 years and 80% by 20 years of age.

H. pylori transmission is primarily by feco-oral route, but saliva and gastric secretions are also infective. Passively transferred immunity offers protection to infants.

Virulence factors help the organism establish itself in the adverse conditions of the stomach. They are of two types—colonization factors and factors responsible for tissue injury. The former include flagella, adherence factor and urease. The flagella help the organism move around in the stomach from areas of low pH to neutral pH to facilitate growth. Adherence factors help the organism to bind to specific receptor on the surface of the gastric epithelium. The organism does not invade the mucosa, but stays on the surface of the epithelium, under the mucus layer. The enzyme urease makes the surrounding environment alkaline by converting urea to ammonia. The factors that induce tissue injury include lipopolysaccharide, leukocyte recruitment and activating factors, vacuolating cytotoxin (VacA) and Cytotoxin-associated antigen (CagA). The first two not only stimulate the release of cytokines, but also have chemotactic properties to recruit and activate monocytes and neutrophils. VacA and CagA are strongly associated with toxin production and more severe inflammatory tissue injury.

DISEASE MANIFESTATIONS

Gastritis and Duodenal Ulcer

H. pylori is etiologically associated with chronic active gastritis, gastric ulcer and duodenal ulcer in children. However, only one in ten *H. pylori* infected persons develop peptic ulcer, while most infected individuals are asymptomatic.

Lymphoma and Adenocarcinoma

Primary gastric B-cell lymphoma, mucosal associated lymphoid type lymphoma (MALT lymphoma) and gastric adenocarcinoma have been reported in adults with chronic infection, but is infrequent in children.

Growth Retardation

The association with growth retardation is mainly from developed countries with little or no evidence from developing countries where the infection is wide spread.

Recurrent Abdominal Pain

Studies to associate recurrent abdominal pain (RAP) with *H. Pylori* over the years have given conflicting results. A recent meta-analysis of 38 studies concluded that there was no association between them. Guidelines from the European Society of Pediatric Gastroenterology, Hepatology and Nutrition (ESPGHAN) and North American Society of Pediatric Gastroenterology, Hepatology and Nutrition (NASPGHAN) support this view. Therefore, routine screening for *H. pylori* is not recommended in children with RAP at least in developing countries.

Iron Deficiency Anemia

There are conflicting reports on *H. pylori* being responsible for iron deficiency anemia (IDA). While studies from Greece, Korea and Turkey have demonstrated a causative effect, two recent studies concluded otherwise. Vendt et al., in a study on 363 children concluded that *H. pylori* seropositivity was not associated with anemia. Sarker et al., in a study from Bangladesh concluded that *H. pylori* was neither the cause of IDA nor a reason for treatment failure of iron supplementation in young children. The possible mechanisms for anemia in *H. pylori* infection include poor absorption of iron due to low gastric acid secretion and consumption of iron by the bacteria itself.

INVESTIGATIONS

Endoscopy-based tests are used for confirmation of *H. pylori* infection, while noninvasive tests are recommended for screening as well as for checking eradication or relapse.

Endoscopy-based Tests

Antral biopsy is required for diagnosis. The *gold standard* for the diagnosis is culture of the gastric mucosal biopsy. However, it is difficult and not routinely available. Rapid urease test (RUT) is easy to perform and has a specificity of around 98%, but the sensitivity is below 90%. This test is based on the unique ability of the organism to produce the enzyme urease which is indicated as a color change. Histology demonstrating *H. pylori* also has a specificity of 98%, but requires a trained pathologist and the sensitivity is below 90%. A combination of RUT and histology is accepted as a diagnostic alternative. Polymerase chain reaction (PCR) is emerging as a diagnostic test of the future.

Noninvasive Tests

Serology is unreliable in young children as the level of antibody produced is unpredictable. In addition, it cannot differentiate present from a past infection, since antibody persists for months after eradication. Both serum and saliva have been used in serology. ^{13}C urea breath test is difficult to perform in children below 5 years. Recently it has been shown that stool ELISA test for *H. pylori* antigen is a good noninvasive test to check eradication. The currently available second generation ELISA test which is based on monoclonal antibodies has a sensitivity and specificity of around 97%. The rapid fecal tests based on immunochromatography using monoclonal antibodies have a sensitivity of 88% and specificity of 93%.

Only those children whose abdominal symptoms are severe enough to suspect organic causes should be investigated. The primary goal is to determine the underlying cause of the symptoms

and not to confirm the presence of *H. pylori*. Therefore, endoscopy is the preferred method of investigation. Diagnostic testing is not recommended in children with functional abdominal pain. Endoscopy may also be selectively recommended for children with refractory iron-deficiency anemia and those whose first-degree relatives have gastric cancer.

TREATMENT

Guidelines from ESPGHAN and NASPGHAN, eradication of the organism is recommended only in children with *H. pylori*—positive peptic ulcer disease (PUD). In those who are positive for *H. pylori* but have no endoscopic lesions, the option of treatment may be offered after an informed discussion with the parents. Parents should be informed of the potential adverse effects of drugs and that eradication of *H. pylori* may not necessarily result in improvement of symptoms. Treatment must also be recommended for children with *H. pylori* infection whose first-degree relative have gastric cancer. Drugs used to treat *H. pylori* are given in **Table 1**.

Conventional first line treatment is twice daily triple drug regimen comprising one proton pump inhibitor (PPI) and two antibiotics (amoxicillin plus clarithromycin or metronidazole) for 10–14 days. Sequential therapy involves a PPI and amoxicillin for 5 days followed by 5 days of triple therapy (a PPI with clarithromycin and metronidazole/tinidazole). Sequential therapy is at least as effective as standard triple drug therapy in children and is considered a first line treatment option (**Table 2**).

Eradication of the organism should be confirmed even if children become asymptomatic after therapy. This should be done 4–8 weeks after completion of treatment with a noninvasive test like ^{13}C urea breath test or a monoclonal ELISA-based stool antigen test. A follow-up endoscopy is not routinely indicated unless the diagnosis is in doubt or if the patient remains symptomatic.

If first line therapy fails to eradicate the organism, repeat biopsy and culture/sensitivity testing is ideal. The treatment schedule may be modified either by adding an antibiotic or bismuth, using a different antibiotic or increasing the duration of therapy. Second line or salvage therapy as given below should be given for up to 14 days.

1. **Quadruple therapy:** PPI + metronidazole + amoxicillin + bismuth
2. **Triple therapy:** PPI + levofloxacin (moxifloxacin) + amoxicillin

Failure of therapy may be due to multiple factors, often acting simultaneously and include: primary antibiotic resistance to clarithromycin, levofloxacin and metronidazole; poor patient compliance; insufficient antibiotic concentration in the cardia of stomach resulting in the organism persisting there; presence of dormant coccoid forms of the bacteria, which are antibiotic resistant; and high bacterial load and presence of VacA and CagA.

Table 1 Drugs used in treatment of *H. pylori* infection in children

Drugs	Dose
Amoxicillin	50 mg/kg/day, max dose: 1 g twice daily
Clarithromycin	20 mg/kg/day, max dose: 500 mg twice daily
Metronidazole	20 mg/kg/day, max dose: 500 mg twice daily
Omeprazole (PPI)	1–2 mg/kg/day, max dose: 20 mg twice daily
Bismuth subsalicylate	< 10 years: 262 mg, > 10 years: 525 mg

Table 2 First line treatment options

A. Triple drug regimen:
1. Amoxicillin + clarithromycin + PPI (e.g., Omeprazole)
2. Amoxicillin + metronidazole + PPI (e.g., Omeprazole)
3. Bismuth subsalicylate + amoxicillin + metronidazole
B. Sequential therapy:
Omeprazole + amoxicillin for first 5 days
Followed by
Omeprazole + clarithromycin + metronidazole for 5 days

The sharp decline in eradication rate over the last decade, with standard regimens has been a major cause of worry. In spite of unraveling the *H. pylori* genome, efforts at vaccine development has stalled in the last decade. Designing a new therapeutic regimen containing a single antibiotic with lesser side-effects that ensures better patient compliance is the challenge for the future.

IN A NUTSHELL

1. Infection with *H. pylori* is common among children in developing countries, but most infected children are asymptomatic.
2. Transmission occurs primarily by feco-oral route and virulence factors decide the severity of infection and inflammation.
3. Chronic gastritis and duodenal ulcer are the only diseases in children with a proven association.
4. The association between *H. pylori* and recurrent abdominal pain is still unproven.
5. Endoscopic antral biopsy and rapid urease test, histology and culture are the preferred method of primary diagnosis.
6. Eradication status may be confirmed with noninvasive tests like ^{13}C urea breath test or monoclonal stool antigen test.
7. First line therapy includes the standard *triple drug regimen* or sequential therapy for 14 days.

Chapter 29.22

Anaerobic Infections

Rekha Harish, Anuj Bhatti

Anaerobes do not multiply in oxygen and have variable susceptibility to oxygen. Most normal flora anaerobes are extremely oxygen sensitive, while those that cause infections are more aerotolerant. The aerotolerance of several anaerobes is through the production of superoxide dismutase, they produce on exposure to oxygen. The negative oxidation–reduction potential (Eh) of the environment is important for their survival.

The exact incidence is difficult to ascertain, as these require special methods to transport, cultivate, isolate and identify. Further, these infections are generally caused by indigenous local microflora invading due to the immunocompromised status of the host. In one of the largest prospective study, they accounted for 5.8% of all bacteremia episodes: 8.7% in the newborn period and 4.8% in children over 1 year of age. The species of anaerobes most frequently isolated from clinical infections in decreasing frequency are as follows:

- Gram-negative rods (*Bacteroides*, *Prevotella*, *Porphyromonas*, *Fusobacterium*, *Bilophila* and *Sutterella*),
- Gram-positive cocci (primarily *Peptostreptococcus*)
- Gram-positive spore-forming (*Clostridium*)
- Nonspore-forming bacilli (*Actinomyces*, *Propionibacterium*, *Eubacterium*, *Lactobacillus*, and *Bifidobacterium*)
- Gram-negative cocci (mainly *Veillonella*).

Important anaerobic infections are listed in **Table 1**. Anaerobes are frequently isolated in combination with other facultative or aerobic bacteria. **Table 2** enlists such exclusive, predominant pathogens in pediatric patients. Certain anaerobes have a predilection for specific anatomical sites. The major anaerobic pathogens in the upper and lower respiratory tract are *Peptostreptococcus* spp., pigmental *Prevotella* and *Porphyromonas*

spp., and *Fusobacterium* spp., *B. fragilis*, anaerobic Gram-positive cocci and *Clostridium* species are frequently isolated from intra-abdominal and female genital infections.

CLINICAL SPECTRUM

Bacteremia

Children with chronic debilitating disorders such as malignancy, immunodeficiency, or chronic renal insufficiency usually present with anaerobic bacteremia. Routine blood cultures are rarely positive for anaerobes in pediatric patients. The strain of anaerobic organisms isolated depends to a large extent on the portal of entry and the underlying disease. *Bacteroides* spp., including *B. fragilis* group, are the predominant isolates when the gastrointestinal tract is the probable portal of entry. The ear, sinus, and oropharynx predisposes to bacteremia by *Peptococcus* sp. and *Fusobacterium* spp.

Skin/Soft Tissue Infections

Common risk factors for the anaerobic infections of the skin and soft tissues are injury by foreign body, ischemia, malignancy, or surgery. The anatomic sites that are subject to fecal or oral contamination are particularly at risk. These include wounds associated with surgery of the intestine or pelvic tract, human bites, decubitus ulcers in the perineal area, pilonidal cysts, omphalitis, and cellulitis. These can present with putrid discharge, gas production, and extensive tissue necrosis with a tendency to burrow through subcutaneous and fascial planes. Infectious gangrene is a rapidly progressive infection that involves extensive necrosis of the subcutaneous tissues and overlying skin. It includes:

- Necrotizing fasciitis (Streptococcal gangrene)
- Gas gangrene (*Clostridium myonecrosis*) and anaerobic cellulitis
- Progressive bacterial synergistic gangrene
- Localized skin necrosis complicating cellulitis
- Gangrenous cellulitis in the immunocompromised patient.

Myonecrosis is a rapidly progressing fatal disease. It requires early and prompt management. The necrotic tissue often needs excision

Table 1 Common organism involved in anaerobic infections in children

Organism	Infectious site
Gram-positive cocci <i>Peptostreptococcus</i> spp. <i>Microaerophilic streptococci</i>	Respiratory tract, intra-abdominal and subcutaneous infections Sinusitis, brain abscesses
Gram-positive bacilli Nonspore-forming <i>Actinomyces</i> spp. <i>Propionibacterium acnes</i> <i>Bifidobacterium</i> spp.	Intracranial abscesses, chronic mastoiditis, aspiration pneumonia, head and neck infections Shunt infections (cardiac, intracranial) Chronic otitis media, cervical lymphadenitis
Spore-forming <i>Clostridium</i> spp. <i>C. perfringens</i> <i>C. septicum</i> <i>C. sordellii</i> <i>C. difficile</i> <i>C. botulinum</i> <i>C. tetani</i>	Wounds and abscesses, sepsis Sepsis Necrotizing infections Diarrheal disease, colitis Botulism Tetanus
Gram-negative bacilli <i>Bacteroides fragilis</i> group (<i>B. fragilis</i> , <i>B. thetaiotaomicron</i>) Pigmental <i>Prevotella</i> and <i>Porphyromonas</i> spp. <i>Prevotella oralis</i> <i>Prevotella B. oris-buccae</i> <i>P. bivia</i> , <i>P. disiens</i> <i>Fusobacterium</i> spp. <i>F. nucleatum</i> <i>F. necrophorum</i>	Intra-abdominal and female genital tract infections, sepsis, neonatal infection Orofacial infections, aspiration pneumonia, periodontitis Orofacial infections Orofacial infections, intra-abdominal infections Female genital tract infections Orofacial and respiratory tract infections, brain abscesses, bacteremia Aspiration pneumonia, bacteremia

Table 2 Infections in which anaerobes are exclusive, predominant or important

Intoxications Tetanus Wound botulism	Neonatal infections Scalp infections Neonatal pneumonia Omphalitis Bacteremia Conjunctivitis of newborn Infant botulism Necrotizing enterocolitis
Head and Neck Chronic and acute otitis media Chronic sinusitis Exudative tonsillitis Tonsillar or pharyngeal abscess Gingivitis Cervical lymphadenitis	Intra-abdominal Complication of appendicitis Peritonitis Pylephlebitis Liver abscess Ascending cholangitis Subphrenic abscess Abscess following visceral perforation Other intra-abdominal abscess Wound infection following abdominal surgery or trauma Complication of diverticulitis
Central nervous system Brain abscess Ventriculitis following neurological shunts Orogenic meningitis, extradural or subdural empyema	
Cardiovascular Bacteremia Endocarditis	
Pleuropulmonary Pneumonia secondary to obstructive process Aspiration pneumonia Lung abscess Bronchiectasis Thoracic empyema	Miscellaneous Breast abscess Gas gangrene (clostridial myonecrosis) Gas forming cellulitis Synergistic necrotizing cellulitis Necrotizing fasciitis Bacterial conjunctivitis

and debridement. Crystalline Penicillin in high-dose (250,000 U/kg/day divided every 4–6 hours IV) is recommended. Alternatively Clindamycin can also be given (25–40 mg/kg/day divided every 6–8 hours IV). Hyperbaric oxygen has been tried but its role in routine clinical settings is not yet proven. Even with early aggressive therapy the prognosis is poor and amputation of affected limbs may be required.

Central Nervous System Infections

Anaerobic organisms are frequently isolated from brain abscess. The spread to the central nervous system can occur from the infections in the contiguous sites like chronic mastoiditis, sinusitis, or otitis media. Seeding from the distant infections (e.g., in lung or abdomen) can occur through hematogenous route. The most common causative organisms are Gram-positive anaerobic cocci, *Bacteroides species* (including *Bacteroides fragilis*), fusobacterium, and actinomyces.

Upper Respiratory Tract/Infections

Chronic infections of the sinuses, ear, periodontal, peritonsillar, parapharyngeal and retropharyngeal areas are associated with anaerobes. Children with poor oral dental hygiene or drug induced hypertrophy of gums are predisposed to have anaerobic periodontal disease.

Vincent's angina (known as acute necrotizing ulcerative gingivitis or trench mouth). It is mixed anaerobic bacterial-spirochetal infection of the gingival margin and floor of the mouth. Children present with acute gingival pain, foul breath, and pseudomembrane formation.

Ludwig angina is a life-threatening infection which originates in the dental region and can rapidly result in airway obstruction caused by cellulitis of the sublingual and submandibular space.

Lemierre syndrome or postanginal sepsis, is a suppurative infection of the lateral pharyngeal space. It usually begins as Epstein Barr Virus or other infections of the pharynx. It later becomes complicated with anaerobic and other polymicrobial organisms which results in unilateral septic thrombophlebitis of the jugular venous system with septic pulmonary embolization. Clinical signs include trismus, unilateral painful neck swelling, and dysphagia with signs of sepsis and respiratory distress. *Fusobacterium necrophorum* is the most common anaerobe involved.

Lower Respiratory Infections

Anaerobes have been isolated from children with aspiration pneumonia, lung abscess, necrotizing pneumonia, and empyema. Normal oral flora is generally reflected in these pleuropulmonary infections. Fistula of the chest wall overlying the intrathoracic infections should provide the characteristic clinical clue. The infections are usually polymicrobial. The organisms include anaerobic gram-positive cocci, *Bacteroides sp.* (including *B. fragilis* and *B. melaninogenicus* groups), *Fusobacterium sp.*, and *Veillonella sp.* In unusual cases, particularly in patients with poor dental hygiene, aspirated oral contents may contain the anaerobe *Actinomyces israelii*, resulting in pulmonary actinomycosis.

Intra-abdominal Infections

Anaerobes outnumber aerobes (1,000:1) in the normal gastrointestinal tract; hence any defect in the intestinal wall/viscus as a result of infarction/obstruction/trauma, would result in the invasion of the peritoneal cavity with anaerobic organisms. Localized or generalized peritonitis will result in abdominal, retroperitoneal, and visceral abscesses, secondary to appendicitis, diverticulitis, necrotizing enterocolitis, pelvic inflammatory disease, and tubo-ovarian infection, surgery, or trauma. Anaerobes are isolated in at least half of cases of pyogenic liver abscess. A colonic source is usually the initial source of infection. The most prevalent anaerobes in liver abscess are anaerobic and microaerophilic streptococci (not true anaerobes), *Fusobacterium spp.*, *B. fragilis* group, and pigmented *Prevotella* and *Porphyromonas spp.*

Typhlitis describes neutropenic enterocolitis of ileo-cecal region which is often a mixed infection. Clinically it is characterized by abdominal pain, diarrhea, fever, and abdominal distention. The clinical course can be dramatic and outcome devastating.

Other Sites

Anaerobic infection in the vicinity of the bone can lead to contiguous infection. Occasionally, anaerobic osteomyelitis, particularly of fingers and toes, be seen in diabetes, neuropathies, vasculopathies, and coagulopathies because these conditions can produce hypoxic necrosis. Anaerobic infections of the heart (pericarditis), kidneys (renal and perirenal abscesses) and are rare. Enteritis necroticans (pigbel) is a rare but often fatal gastrointestinal infection that most commonly follows ingestion of a large meal in a previously starved child or adult.

Neonatal Infections

Anaerobic neonatal bacteremia is estimated to occur in 1.8 cases per 1,000 livebirths. Prolonged labor, premature rupture of membranes, amnionitis, prematurity, fetal distress, and respiratory difficulty are attributed maternal risk factors predisposing to bacteremia. Most often isolated organisms are *Bacteroides sp.*, *Clostridium sp.*, and *Fusobacterium nucleatum*. Anaerobes are also implicated in necrotizing enterocolitis. They have also been isolated from other neonatal infections viz. conjunctivitis, omphalitis and pneumonia. Neonatal tetanus is discussed elsewhere in the book.

Infantile Botulism

Infantile botulism is occasionally encountered in this part of the world due to common practice of giving honey as prelacteal feed to the newborn. It is caused by absorption of heat-labile neurotoxin produced by *Clostridium botulinum*. The toxin does exert its toxicity through affecting the transmission at all peripheral cholinergic junctions. It does not cross blood brain barrier but blocks the release of acetylcholine from the nerve terminal in response to depolarization. The main clinical feature of the syndrome is constipation (95%) and lower motor neuron symmetric, descending paralysis. Cranial nerve palsy is often the first clinical manifestation presenting with drooling, weak cry/suck or subdued facial expression as the common initial symptoms.

The time between the onset of constipation and onset of weakness ranges from 0 to 24 days (mean 11 days). Progression is more severe in infants especially less than two months. Autonomic dysfunction is quite common. Parasympathetic nervous system is more vulnerable to cholinergic blockade. The clinical manifestations may include decreased salivation, distension of abdomen and bladder, decreased bowel sounds, and fluctuations in blood pressure, heart rate, and skin color. Respiratory support may be required, though often in first week. Diagnosis is mainly on clinical grounds as stool samples for spores and toxins are often unavailable and culture takes up to 6 days for a positive yield. There is no role of antibiotics as they may increase the pool of toxin in bowel by causing bacterial lysis). Botulism Immune Globulin (BIG IV) a human derived antitoxin was conclusively demonstrated to be beneficial in a recent RCT in California.

Diagnosis is purely on clinical grounds. Respiratory support may be required in first week of illness. There is no role of antibiotics as they may increase the pool of toxin in bowel for absorption (toxin liberated after bacterial cell death).

DIAGNOSIS

High index of clinical suspicion is required to recognize the risk factors for anaerobic infections. Anaerobes form normal microflora at the skin and mucosal tissues, hence the swab samples from skin and mucosal surfaces and various secretions are not recommended. Aspirates of infected sites, abscess material, and biopsy specimens may reveal organisms. The samples must be transported immediately to the laboratory. The use of anaerobic transport medium is helpful. Gram staining of abscess fluid from suspected anaerobic infections is helpful even if the organisms do not grow in culture.

TREATMENT

The principles of managing anaerobic infections include

1. Neutralization of toxins
2. Prevention of local proliferation
3. Prevention of spread into healthy tissues.

Antitoxins can be used for the neutralization of toxin in tetanus and botulism. Debridement of necrotic tissue and draining of pus can prevent the local proliferation of anaerobes. Antibiotics can be used to avoid local proliferation and spread of infection. Penicillin still remains the preferred drug for the anaerobes of oral origin. β -lactamase production is the most common mechanisms of resistance to Penicillin by these organisms. In these scenario

metronidazole, penicillins combined with β -lactamase inhibitors (ampicillin-sulbactam, ticarcillin-clavulanate, and piperacillin-tazobactam), carbapenems (imipenem and meropenem), clindamycin, and cefoxitin are effective. Antibiotics for anaerobic infections should be given for prolonged periods because of their tendency to relapse (up to 3 weeks in serious infections). Role of hyperbaric oxygen in the treatment of anaerobic infections still remains uncertain.

PREVENTION

Prophylactic use of antibiotics against anaerobes is recommended in all elective intra-abdominal and oropharyngeal surgeries. Cefoxitin is the preferred drug for these conditions.

Superficial wounds suspected to be caused by anaerobes should be irrigated copiously and allowed to heal by secondary intention, especially if they are ragged lacerations caused by animal or human bites.

IN A NUTSHELL

1. Anaerobic infections are frequently caused by indigenous local microflora invading human body secondary to the immunocompromised status, breach in mucosa or presence of foreign body.
2. They should be clinically suspected in any foul-smelling lesion/discharge, black discoloration of exudate, *sulfur granules* in discharge, necrotic gangrenous tissue or evidence of free gas in tissue; cases of bacteremia/endocarditis without any growth on aerobic blood cultures.
3. Swab samples from skin and mucosal surfaces and various secretions are not recommended for diagnosing anaerobic infections. However, aspirates of infected sites, abscess material and biopsy specimens may reveal organisms.
4. Debridement of necrotic tissue and drainage of pus is a useful adjunct along with antibiotics to curtail local proliferation.
5. Rational Antibiotic stewardship in aerobic infections have been effective in reducing the rates of *C. difficile anaerobic* infection, an anaerobic infection which is currently a rising cause of health-care associated infections.

Section 30 MYCOBACTERIAL INFECTIONS

Section Editor Soumya Swaminathan

Chapter 30.1

Antitubercular Drugs

Geetha Ramachandran

Mycobacterial infections represent some of the most difficult diseases to treat; because of the rich lipid content and a complex cell envelope, mycobacteria are refractory to most antimicrobial agents. In addition, mycobacteria are facultative intracellular parasites, capable of surviving and persisting within the host macrophage. Given this intracellular infestation, agents that are to be effective in controlling and/or killing the pathogen must also be able to penetrate the host cell that harbors the mycobacteria. Intracellular effectiveness is therefore an additional attribute necessary for adequate antimycobacterial therapy. The chronic nature of mycobacterial infections generally necessitates prolonged therapy over several months. An ideal agent should therefore have low toxicity and be effective at low dose levels. The slow growing nature of the microorganisms, adherence to treatment, adverse events and drug resistance pose therapeutic challenges.

DRUGS

Four groups of organisms can be found in patients infected with tuberculosis (TB)—(1) actively growing extracellular organisms, which are present in large numbers in aerated cavities (2) intermittent slowly growing organisms in the infected site (3) organisms surviving environmental conditions with low pH and (4) fully dormant organisms surviving in anaerobic conditions. The key actions of anti-TB drugs are:

- Bactericidal action, indicating their capacity to kill actively growing bacilli;
- Sterilizing action, indicating their ability to kill semi-dormant organisms;
- Preventing the emergence of resistance.

Anti-TB drugs differ in their ability to kill actively metabolizing extracellular population (bactericidal), their action on semi-dormant bacilli (sterilizing action) and in prevention of emergence of resistant strains. The different groups of drugs used to treat TB are shown in **Table 1**. *First-line* agents possess a high-degree

of efficacy with minimal toxicity and *second-line* agents having either less efficacy, greater toxicity or both. Patients infected with TB can be cured of the disease by treatment with first-line drugs. Occasionally, however, because of bacterial resistance or patient-related factors, it may be required to change to second-line drugs.

The modern short-course chemotherapy aims at rapid bactericidal and sterilizing action. Combination chemotherapy is employed because of the usual presence of spontaneously resistant mutants to one drug, which, with single drug therapy, may multiply and replace the killed microorganisms. Improper chemotherapy leads to acquired drug resistance. Children usually do not depict primary resistance unless the source case is suffering with resistant bacilli.

Isoniazid

Isoniazid (INH), hydrazide of isonicotinic acid was introduced in clinical practice in 1952. It is a first-line drug used to prevent and treat TB. It is quite cheap and well-tolerated. It is bactericidal to rapidly multiplying mycobacteria, and is bacteriostatic to slow growing mycobacteria. The minimal bacteriostatic concentration of INH is 0.025–0.05 µg/mL. It is remarkably selective for mycobacteria. *Mycobacterium kansasii* is the only nontuberculous mycobacteria that is susceptible to isoniazid. INH inhibits the synthesis of mycolic acid which is an essential mycobacterial cell wall component.

Metabolism

Isoniazid attains therapeutic concentrations in blood, cerebrospinal fluid (CSF) and caseous granulomas. It undergoes acetylation in the liver by N-acetyl transferase. There are two forms of the enzyme which bring about this reaction; fast metabolizers, who acetylate INH rapidly than others, the half-life being bimodal. The rate of acetylation is genetically determined. Thus, rapid acetylators metabolize INH faster than slow acetylators, the former having 4–5 times higher quantity of the enzyme than slow acetylators. Isoniazid acetylator status can be determined using phenotypic or genotypic methods. The distribution of rapid and slow acetylators of INH differs across different racial and ethnic populations. The frequency of the slow allele has been reported as 10% in people belonging to the mongoloid race such as Eskimos, Japanese, Chinese, 90% in Middle East, 60% in the Negroid, Caucasian and south Indians, and 72% in the USA.

Table 1 Groups of drugs used to treat tuberculosis

Group	Group name	Drugs
1	Oral first-line agents	Isoniazid (INH), rifampicin, ethambutol, pyrazinamide, rifabutin, rifapentine
2	Injectables	Kanamycin, amikacin, capreomycin, streptomycin
3	Fluoroquinolones	Moxifloxacin, levofloxacin, ofloxacin
4	Oral bacteriostatic second-line agents	Ethionamide, prothionamide, cycloserine, terizidone, para-amino salicylic acid
5	Others with unclear efficacy	Clofazimine, linezolid, amoxicillin-clavulanic acid, thiacezone, meropenem-clavulanic acid, imipenem/cilastatin, high-dose INH, clarithromycin

Adverse Events

Peripheral neuropathy and central nervous system (CNS) effects are common side-effects because of the use of INH due to pyridoxine (vitamin B₆) deficiency. The hepatotoxic side-effects due to INH have been reported to be caused by the N-acetyl hydrazine metabolite. Further, it has been demonstrated that slow acetylators are likely to be affected more than rapid acetylators.

Pharmacokinetics

Isoniazid is absorbed readily through oral or parenteral administration. Aluminum containing antacids could interfere in the absorption. Peak plasma concentrations of about 3–5 µg/mL are achieved at about 1–2 h. INH readily diffuses into all body fluids and cells. The drug can be detected in pleural fluid and ascitic fluid, and plasma and CSF concentrations are similar. INH penetrates into caseous material and is not bound to serum proteins; hence plasma and saliva concentrations are similar. About 75–95% of INH is excreted within 24 hours in the urine as metabolites.

Rifampicin

Rifampicin, also known as rifampin belongs to the rifamycin group, and came into use in 1967. It is bactericidal and inhibits growth of most Gram-positive and Gram-negative microorganisms. It is an important component of first-line treatment regimen of tuberculosis. It inhibits growth of *Mycobacterium tuberculosis* at concentrations of 0.005–0.2 µg/mL in vitro. It inhibits growth of certain nontuberculous mycobacteria such as, *M. kansasii*, *Mycobacterium avium*, *Mycobacterium intracellulare* and *Mycobacterium scrofulaceum*. Rifampicin, being red, imparts a red-orange color to body excretions, predominantly urine and sweat and tears to a lesser extent after intake. Serum drug concentrations are reduced when the drug is taken along with meal.

Mechanism of Action

Rifampicin acts by inhibiting ribonucleic acid (RNA) synthesis in the bacteria by blocking the bacterial DNA-dependent RNA polymerase, thereby suppressing initiation of chain formation. Rifampicin resistance develops quickly during treatment; as a result of mutations that modify rifampicin binding site on the polymerase, leading to reduced affinity for rifampicin. Resistant mutations have been mapped to the *rpoB* gene, which encodes the beta subunit of RNA polymerase.

Adverse Effects

Hepatotoxicity is the most important adverse effect and patients treated with this drug should get their liver function tested at frequent intervals. Further, in view of being an effective liver enzyme-inducer, rifampicin administration can also lead to other adverse reactions when used with other medications. The other common side-effects include fever, rashes, gastrointestinal disturbances and immunological reactions. Rifampicin is excreted in breastmilk.

Pharmacokinetics

Rifampicin is readily absorbed from the gastrointestinal tract; maximal concentrations of about 7 µg/mL are attained at 2–4 hours after intake of 600 mg per dose. Aminosalicic acid may delay the absorption reduce drug levels. Following absorption, rifampicin is eliminated through the bile by enterohepatic circulation. During this process, the drug gets deacetylated; the deacetylated product has full antibacterial activity. About 30% of the drug is excreted in urine. Rifampicin gets distributed in effective levels in many organs and body fluids, such as the CSF.

Pyrazinamide

Pyrazinamide, a synthetic pyrazine analog of nicotinamide is a first-line drug used to in the treatment of tuberculosis. It is bactericidal at a slightly acidic pH and kills organisms residing within monocytes at a drug concentration of about 12.5 µg/mL.

Mechanism of Action

Pyrazinamide is a prodrug which inhibits growth of *M. tuberculosis* by diffusing into the bacilli, where it gets converted to the active form, pyrazinoic acid by the enzyme, pyrazinamidase. Mutations in the *pncA* gene, which codes for pyrazinamidase, leads to pyrazinamide resistant *M. tuberculosis* strains. Certain pyrazinamidase resistant strains with mutations in the *rpsA* gene have also been reported. Pyrazinoic acid accumulation impairs membrane potential and interferes in energy production, essential for bacterial survival at the site of infection. Pyrazinoic acid inhibits translation by binding to ribosomal protein S1, which explains the ability of pyrazinamide to kill dormant mycobacteria.

Adverse Effects

The most common adverse event of pyrazinamide is joint pains (arthralgia); however, this is usually not very severe, requiring patients to stop taking this drug. Pyrazinamide can cause gout by reducing renal excretion of uric acid. Another serious adverse event is hepatotoxicity, which is dose-related. Other adverse effects include anorexia, nausea and vomiting, skin rash, sideroblastic anemia, pruritus, and urticaria.

Pharmacokinetics

Pyrazinamide is readily absorbed through the gastrointestinal tract and is distributed widely throughout the body. Serum concentrations of about 45 µg/mL are attained at 2 hours following oral administration of 1 g of pyrazinamide. The primary route of elimination is renal. Pyrazinamide undergoes hydroxylation to pyrazinoic acid and then to 5-hydroxy pyrazinoic acid, which is the main excretory product.

Ethambutol

Mechanism of Action

Ethambutol (EMB) is bacteriostatic and is also effective against *M. avium complex*, and *M. kansasii*. Ethambutol exerts its action by inhibiting cell wall formation. Mycolic acids get attached to 5'-hydroxyl groups of D-arabinose residues in arabinogalactan, forming mycolyl-arabinogalactan-peptidoglycan complex. It prevents synthesis of arabinogalactan by disrupting arabinosyl transferase.

Adverse Effects

The most important adverse event is optic neuritis, causing visual acuity and loss of ability to differentiate red and green, this being dose related and reversible. The drug enhances blood urate concentrations because of reduced renal excretion of uric acid.

Pharmacokinetics

About 75–80% of an orally administered dose is absorbed through the gastrointestinal tract. Plasma concentrations of about 5 µg/mL are attained at 2–4 hours following a single dose of 15 mg/kg. The half-life of ethambutol is 3–4 hours. About two-thirds of an ingested dose of ethambutol is excreted unchanged in the urine within 24 hours; about 15% is excreted as two metabolites, namely aldehyde and a dicarboxylic acid derivative. It is well distributed in fluids and body tissues.

Aminoglycosides

Streptomycin was the first antibiotic used to cure tuberculosis. It is bactericidal and can inhibit growth of *M. tuberculosis* at concentrations as low as 0.4 µg/mL. Amikacin, kanamycin and capreomycin have limited antitubercular activity in acid environments. Further, their limited ability to target intracellular organisms means that they have poor activity against *M. tuberculosis* residing within host macrophages, which may explain lack sterilizing activity in vivo. Thus, these antibiotics are part of second-line of treatment of tuberculosis.

Mechanism of Action

Aminoglycosides are protein synthesis inhibitors. They exert their action by binding to 16S rRNA of the 30S subunit of the bacterial ribosome, thereby interfering with binding of formyl-methionyl-tRNA to the 30S subunit. This causes codon misreading, inhibition of protein synthesis and finally bacterial cell death.

Adverse Effects

The common adverse events are nephrotoxicity, ototoxicity, vestibular toxicity and electrolyte abnormalities. The vestibular portion of cranial nerve VIII (the vestibulocochlear nerve) is affected, leading to tinnitus, ataxia and vertigo.

Pharmacokinetics

Aminoglycosides are absorbed completely after injection. They are known to cross poorly into CSF, but diffuse into bronchial secretions. About 99% of aminoglycosides get excreted in the urine as the parent drug. Aminoglycosides are minimally protein bound and highly water-soluble, explaining their limited ability to cross lipid-containing membranes. The aminoglycosides show concentration dependent killing; 1 g intramuscular dose produces peak plasma concentrations of 25–30 µg/mL.

Ethionamide

Mechanism of Action

Ethionamide is a second-line drug used to treat drug-resistant tuberculosis. Drug concentrations of about 0.6–2.5 µg/mL can suppress multiplication of *M. tuberculosis*. It is a prodrug, which gets activated by a monooxygenase, namely ethA, present in *M. tuberculosis*; this binds to NAD⁺ causing inhibition of InhA.

Adverse Effects

The most common adverse events are anorexia, vomiting and nausea and can cause a metallic taste. Ethionamide shares structural similarity with methimazole, and has been reported to inhibit thyroid hormone synthesis. This could lead to hypothyroidism.

Pharmacokinetics

Oral administration of 1 g of ethionamide produces maximal plasma concentrations of about 20 µg/mL at 3 hours. Its half-life is about 2 hours. Ethionamide is widely distributed; concentrations in blood and various organs are similar. Significant levels are present in CSF. Only about 1% of ethionamide is excreted unchanged in the urine.

Para-aminosalicylic Acid

Although para-aminosalicylic acid (PAS) is less potent compared to INH, rifampicin, ethambutol, pyrazinamide, and streptomycin, it is still useful to treat multidrug-resistant tuberculosis. PAS is a prodrug and gets incorporated into the folate pathway to generate a hydroxyl dihydrofolate antimetabolite, which in turn blocks dihydrofolate reductase (DHFR) enzymatic activity.

Side Effects

Nausea, vomiting, and diarrhea are common; the delayed-release formulation can overcome this problem. It can cause drug-induced hepatitis. Patients with glucose-6-phosphate dehydrogenase deficiency should not be prescribed aminosalicylic acid, since it can cause hemolysis. Goiter can also be encountered, due to inhibition of synthesis of thyroid hormones by aminosalicylic acid. Phenytoin levels are likely to increase because of drug interactions. Rifampicin coadministration leads to reduction in rifampicin concentrations by 50%.

Pharmacokinetics

Para-aminosalicylic acid is rapidly absorbed from the gastrointestinal tract. A single oral dose of 4 g of the free acid leads to peak plasma concentrations of about 75 µg/mL at 1.5–2 hours. The drug gets distributed throughout the total body water and attains high concentrations in pleural fluid and caseous tissue. The drug has a short half-life of 1 hour, and plasma concentrations become negligible within 4–5 hours. About 50% of the drug is excreted in urine, more than 50% as acetylated metabolite. Excretion of PAS is impaired during renal dysfunction and is not recommended in such patients.

Cycloserine

Cycloserine is an antibiotic and a second-line drug used to treat drug-resistant tuberculosis. It is capable of penetrating into the CNS. Cycloserine exerts its action by inhibiting bacterial cell-wall biosynthesis. Cycloserine, at large doses increase the risk of occurrence of seizures and is contraindicated in persons with a history of epilepsy. It is readily absorbed following an oral dose. Maximal plasma concentrations are attained at about 3–4 hours and are in the range of 20–35 µg/mL. It is distributed throughout tissues and body fluids. Concentrations in CSF and plasma are similar. Toxic concentrations may accumulate in patients with impaired renal function.

Fluoroquinolones

The potency of fluoroquinolones against *M. tuberculosis* is as follows: moxifloxacin above levofloxacin above ofloxacin, with levofloxacin having at least twice the activity of ofloxacin. Of note, the activity of levofloxacin and ofloxacin against bacterial pathogens are decreased 4–16 fold at an acidic pH of 5.0. These drugs have also shown in vitro activity against intracellular bacteria. Fluoroquinolones are well-tolerated, common adverse events being gastrointestinal disturbances, CNS manifestations, prolongation of QT interval and arthropathy. These are readily absorbed following oral administration, with bioavailability of 85–95% for ofloxacin, more than 99% for levofloxacin and 86–91% for moxifloxacin. Absorption is substantially reduced by coadministration of multivalent cations. Food can delay absorption and lower peak concentrations. The fluoroquinolones have good penetration into body fluids, including CSF.

Linezolid

Linezolid has demonstrated consistent in vitro activity against *M. tuberculosis*. It has shown intracellular activity against *M. tuberculosis*, and its activity in a murine model being less than that of rifampicin but greater than that of INH. Linezolid has bactericidal activity against drug-susceptible strains in the exponential growth phase, but against nonreplicating *M. tuberculosis* in a latent growth phase, only the highest concentrations showed any bactericidal activity, suggesting limited sterilizing ability. Adverse events associated with its use are GI disturbances, hematologic toxicity, and neurotoxicity. Linezolid is rapidly absorbed with an oral

Table 2 Doses of first-line anti-TB medications for children

Drug	Daily dosage (mg/kg)	Intermittent dosage (mg/kg)	Therapeutic range (µg/mL)	Route of elimination
INH	10	15	3–6	Renal
Rifampicin	15	15	8–24	Biliary
Pyrazinamide	35	35	20–50	Renal
Ethambutol	15	30	2–6	Renal
Streptomycin	15	30	35–45	Renal

Table 3 Dosages of second-line anti-TB drugs for children and therapeutic range

Drug	Dose recommended (mg/kg)	Maximum dose	Therapeutic range (µg/mL)
Kanamycin	15–30 once daily	1 g	35–45
Amikacin	15–22.5 once daily	1 g	35–45
Capreomycin	15–30 once daily	1 g	35–45
Ofloxacin	15–20 once daily	800 mg	8–12
Levofloxacin	7.5–10 once daily (twice daily for < 5 years)	750 mg	8–12
Moxifloxacin	7.5–10 once daily	400 mg	3–5
Ethionamide	15–20 once daily	1 g	1–5
Cycloserine	10–20 once or twice daily	1 g	20–35
PAS	150 daily in 2–3 divided doses	12 g	20–60
Linezolid	10 twice daily (once daily for > 10 years)		Not known

bioavailability of 100%. A high-fat meal may delay absorption and reduce peak concentration. Linezolid has good tissue penetration, including lung and epithelial lining fluid.

Tables 2 and 3 summarize the dosages of first and second-line anti-TB agents for use in children.

NEW DRUGS

TMC 207

TMC 207 belongs to a new chemical family and targets adenosine triphosphate (ATP) synthase, causing inadequate synthesis of ATP. It has a minimum inhibitory concentration (MIC) of 0.06 µg/mL against *M. tuberculosis* and does not have any cross resistance with existing anti-TB drugs. The activity of TMC 207 is time-dependent and depends on the duration of the active concentration of the drug remaining greater than the MIC. At concentrations 10 times and 100 times the MIC, the drug was observed to be highly bactericidal against *M. tuberculosis*, which was observed after 6 days of incubation. The effectiveness and safety of TMC 207 have not been studied adequately in children. According to the Centers for Disease Control and Prevention (CDC), TMC 207 may be used on a case-by-case basis in children when an effective treatment regimen cannot be otherwise provided.

Nitroimidazopyrans

Nitroimidazo-oxazine PA-824

PA-824 is currently among the more promising new drugs used to treat tuberculosis. It is a derivative of metronidazole. PA824 has potent anti-TB activity, with MIC of 0.125 µg/mL against drug-susceptible and resistant strains of *M. tuberculosis*. It is bactericidal against both replicating and nonreplicating bacilli. It inhibits synthesis of ketomycolates, which is an essential component of the mycobacterial cell wall.

OPC-67683 (Delamanid)

OPC-67683, a nitro-dihydro-imidazooxazole, is a derivative of metronidazole. Its drug action is similar to that of PA 824 and MIC against *M. tuberculosis* ranges is about 10 times lower than the MIC of PA824. It also has potent activity against intracellular *M. tuberculosis*. However, its bioavailability is 10 times less than PA824. Clinical trials in children using delamanid are in progress in South Africa.

SQ109

SQ109 is an analog of ethambutol. It has a MIC of 0.5 µg/mL for *M. tuberculosis* and does not have cross resistance with ethambutol. It targets the formation of cell wall by inhibition of trehalose monophosphate transferase. It possesses anti-TB activity when used singly and also when combined with other drugs.

Benzothiazinones and Dinitrobenzamides

Drug susceptible and MDR TB are uniformly susceptible to these drugs. These compounds target enzymes required for synthesis of arabinans, which are essential parts of the cell wall.

IN A NUTSHELL

1. Intracellular effectiveness is an additional attribute necessary for adequate antimycobacterial therapy.
2. The chronic nature of mycobacterial infections generally necessitates prolonged therapy over several months.
3. An ideal agent should have low toxicity and be effective at low-dose levels. The slow growing nature of the microorganisms, adherence to treatment, adverse events and drug resistance pose therapeutic challenges.
4. First-line drugs include INH, Rifampicin, Pyrazinamide, Ethambutol, and Streptomycin.
5. Important second-line drugs include ethionamide, cycloserine, other aminoglycosides, fluoroquinolones, PAS and linezolid.

Chapter 30.2

Tuberculosis

Soumya Swaminathan, N Pooranagangadevi,
Ben J Marais

Tuberculosis (TB) is a major cause of disease, both pulmonary and extrapulmonary and death in young children in India, reflecting the high disease burden in adults. Major risk factors include poverty with associated undernutrition, overcrowding and human immunodeficiency virus (HIV) infection. This chapter reviews the disease burden and the natural history of disease in children with TB and describes the current status of diagnosis, treatment and prevention of TB in children.

DISEASE BURDEN

Most cases of TB in children occur in the TB-endemic countries but the actual burden of childhood TB is unknown. In 2012, WHO estimated that globally there were 530,000 TB cases among children (under 15 years of age), and 74,000 TB deaths (among HIV negative children), 6% and 8% of the global totals, respectively. India has one of the highest TB burdens globally, accounting for 25% of the 8.6 million new TB cases annually. While the burden of childhood TB in India is not known, regional data from the World Health Organization (WHO) indicate that sputum microscopy smear-positive TB in children (< 14 years old) accounts for 0.6–3.6% of all reported cases.

In 2013, 85,000 children were diagnosed and treated in the Revised National TB Control Program (RNTCP), accounting for ~7% of total TB cases in the public sector in India. This proportion has been fairly stable over the past few years. However, because the majority of children are sputum microscopy smear negative, these figures underestimate the true burden of childhood TB. It is estimated that childhood TB constitutes 10–20% of all TB in high-burden countries, accounting for 8–20% of TB-related deaths. Further, many young children with extrapulmonary and more severe forms of TB are probably treated in the private sector and data regarding these cases is not available in the public domain. A recent modeling paper suggests that India accounts for 27% (22–33) of the total burden of pediatric TB in the high burden 22 countries.

A nationwide survey in India among young children showed very high figures of annual risk of *Mycobacterium tuberculosis* infection in almost all the regions—highest in north zone (1.9%) followed by west zone (1.8%), east zone (1.3%) and lowest in the south zone (1.1%). HIV infection increases susceptibility to infection with *M. tuberculosis*, the risk of progression from infection to TB disease as well as reactivation of latent TB. Increasing levels of co-infection with TB and HIV in children have been reported from countries with dual epidemics, with prevalence of HIV in TB-infected children ranging from 10% to 60%. Management of both infections poses a challenge to clinicians.

Children serve as a *sentinel*, reflecting ongoing TB transmission in the community, and drug resistance in this group mirrors the situation in the adult population in the region. The occurrence of drug-resistant TB (DR-TB) among children has been documented by several groups. In the Western Cape, repeat surveys among children, done in 1997–1998, 2001–2002 and again in 2005–2006, showed that resistance to isoniazid (INH) or rifampin (RIF) increased from 6.9% to 12.9% to 15.1% and multidrug resistance from 2.3% to 5.6% to 6.7% respectively. Drug resistance among children

has been documented in both pulmonary and extrapulmonary disease. The Global TB Report 2013, reviewing data from many countries reporting drug resistance survey and surveillance data, concluded that *drug resistance is as likely among children as among adults*. In India, the few reports available indicate that DR-TB does occur in children, with the rate reflecting the DR-TB rates in adults in that geographic region. **Table 1** summarizes key differences between adults and children with TB.

Human immunodeficiency virus co-infection has had a major impact on the epidemiology of TB, especially in sub-Saharan Africa. In addition to an increase in the absolute number of TB patients, HIV induced a pronounced shift in the age and gender profile of TB patients with more young adults and women of child-bearing age being affected. This has resulted in increased TB exposure of young and vulnerable children living in HIV-affected households, as shown by high rates of TB exposure within the first 6 months of life in babies born to HIV-infected mothers, and high disease rates among HIV-infected infants in South Africa.

In India, because HIV prevalence in the population as well as among pregnant women is low (approximately 0.3%), the epidemiology of TB has not been affected much. However, at the individual level, in HIV-affected households, both adults and children are at higher risk of TB. Regular screening for TB, early diagnosis and treatment of active disease and preventive therapy should be implemented widely in order to reduce the burden of TB among HIV-infected individuals.

NATURAL HISTORY OF DISEASE

Figure 1 shows the schematic timeline following primary pulmonary infection with *M. tuberculosis*. Pulmonary infection occurs when a few bacilli reaches a terminal airway and establish infection. A localized inflammatory process occurs within the lung, referred to as the primary (Ghon) focus, from where bacilli drain via lymphatics to the regional lymph nodes. Before acquired immune responses are able to control and localize the infection, bacilli enter the systemic circulation via the regional lymph nodes with occult hematogenous spread. Bacilli can survive in various organs for prolonged periods depending on local conditions and pathogen-host interactions.

Age is an important variable, and the youngest of all children have the most rapid disease progression. The clinical syndromes associated with primary *M. tuberculosis* infection in children are summarized in the following phases:

- **Phase 1** occurs 3–8 weeks after primary infection and usually presents with fever, a visible primary complex on chest radiograph (CXR) and hypersensitivity manifestations such as erythema nodosum and tuberculin skin test (TST) conversion. This stage may be relatively asymptomatic and is often missed.
- **Phase 2** occurs 1–3 months after primary infection and follows hematogenous spread. This represents the period of highest risk for the development of tuberculous meningitis (TBM) and disseminated (miliary) TB in young children, though these can occur at any time.
- **Phase 3** occurs 3–7 months after primary infection and manifests as intrathoracic lymph node enlargement in young children (< 5 years of age) and reactive pleural effusions in older children.
- **Phase 4** lasts for 1–3 years after primary infection. It represents the period of osteoarticular TB in children under 5 years of age and adult-type disease in adolescents. The risk of disease progression is least between 5 years and 10 years of age.
- **Phase 5** more than 3 years after primary infection. By this time the highest risk period has passed, although delayed onset adult-type TB may present in adolescents.

Table 1 Differences between adult and childhood tuberculosis

Aspect	Adults	Children
Epidemiology	Relatively well-quantified burden—2.1 million new cases each year in India, of which ~1.5 million in RNTCP	Poorly quantified global and country disease burden—~85,000 cases/year in RNTCP
Pathogenesis	Usually <i>adult-type</i> lung disease	Usually intrathoracic lymph node disease, but extra-pulmonary disease common
Transmission	Lung cavitary disease highly infectious	Paucibacillary disease; epidemiologic marker of transmission
Drug resistance	Acquired drug resistance more common	Usually primary (transmitted) drug resistance
Exposure history	May not be contributory	Essential part of diagnostic work-up
Risk of progression to disease	Relatively low risk of progression to disease following TB exposure/infection unless immunocompromised	Greatest risk of progression in the very young and/or immunocompromised
Preventive therapy	Not recommended, except in immunocompromised adults	Definite value in young (< 5 years of age) contacts and all immunocompromised children
Imaging	Chest radiographs (CXR) required, only if sputum negative for AFB	CXR (with both anteroposterior and lateral views, of good quality, and properly read) is important investigation
Microbiological studies	Sputum smear microscopy for AFB first test. Xpert MTB/Rif recommended in sputum smear negative, HIV+, retreatment and other patients at high risk for MDR-TB	Gastric aspirate or induced sputum must be collected (young children cannot expectorate); Xpert MTB/Rif has better yield than smear
Treatment (drug-susceptible TB)	With four drugs in intensive phase.	With three or four drugs depending on likelihood of isoniazid resistance and HIV co-infection
Pharmacokinetics	Acetylator status influences isoniazid levels	Younger age and stunting also lower blood levels of anti-TB drugs. Faster metabolism in young children alters PK
Prognosis	Good outcomes with timely and appropriate treatment	Excellent outcomes achievable; long-term sequelae common with delayed diagnosis, especially tuberculosis meningitis

Abbreviations: RNTCP, Revised National TB Control Program; TB, tuberculosis; MDR-TB, multidrug resistance tuberculosis; PK, pharmacokinetics; AFB, acid-fast bacillus; CXR, chest radiographs.

Figure 1 Schematic timeline following primary pulmonary infection with *M. tuberculosis*

Adapted timeline of tuberculosis:

- 0 Incubation
- I Tuberculin skin test conversion
- II Ghon focus and/or disseminated (miliary) disease
- III Lymph node disease (< 5 years of age)/pleural effusion (> 5 years of age)
- IV Adult-type disease (> 10 years of age)

DISEASE SPECTRUM

Intrathoracic Disease

Pulmonary involvement in children presents with a diverse spectrum of pathology that can be visualized on CXR. However, CXR is not a very sensitive tool and many parenchymal and lymph node lesions can be missed. Taking anteroposterior (AP) as well as lateral views and using a standardized disease classification system is important for management as well as for reporting.

Primary (Ghon) focus The primary focus is usually single, though there may be multiple foci, which are variable in size and which may show an overlying pleural reaction. Local complications

include parenchymal destruction with cavity formation, as well as intrabronchial spread with bronchopneumonic consolidation (**Figs 2 and 3**).

Lymph node disease Involvement of the intrathoracic lymph nodes (perihilar and/or paratracheal) (**Figs 4 and 5**) is considered the radiological hallmark of primary infection. Lymph nodes can rupture into airways, or compress them from outside; such complications are most common in young children because of smaller airways. Airway compression results when the trachea or main bronchus is surrounded by diseased lymph nodes; best visualized on an overpenetrated CXR. Various disease presentations include partial airway obstruction with a check-valve effect and alveolar hyperinflation, or total airway obstruction with alveolar collapse. Caseating pneumonia often causes an expansile pneumonic process with visible parenchymal breakdown. Rare complications include diaphragmatic palsy, broncho- or tracheoesophageal fistula, and a unilateral chylothorax.

Pleural or pericardial effusion Effusions represent a hypersensitivity response to TB antigens (**Fig. 6**). Isolated pleural effusions are unusual in children more than 3 years of age and tend to develop within a few months after primary infection. TB empyema occurs when bacteria multiply within a loculated fluid collection. Pleural effusion can be diagnosed on CXR and ultrasound and confirmed by examining aspirated fluid (high protein and lactate dehydrogenase, lymphocytic pleocytosis). Pericardial effusion usually develops when a subcarinal lymph node erupts into the pericardial space. Ultrasound is the most sensitive test to confirm a pericardial effusion; constrictive pericarditis can develop later.

Disseminated disease Though dissemination is common following primary infection, it rarely progresses to disseminated disease

Figure 2 Parenchymal destruction with cavity formation

Figure 4 Perihilar lymph nodes

Figure 3 Intrabronchial spread with bronchopneumonic consolidation

except in very young (<2-3 years of age) and immunocompromised children. CXR is usually diagnostic of miliary disease with even-sized miliary lesions (<2 mm) distributed bilaterally into the very periphery of the lung. In HIV-infected children, the differential diagnosis includes lymphocytic interstitial pneumonitis (LIP) and opportunistic infections such as *Pneumocystis jiroveci* pneumonia (PCP), which have a similar radiological picture. The presence of parotid enlargement, clubbing and generalized superficial lymphadenopathy is more suggestive of LIP, while children with PCP are dyspneic and sick. A trial of antibiotics may have to be given to distinguish between these conditions.

Adult-type disease Adult-type disease is common during adolescence, but can occur from 8 years onward. Similar to adults, the apical and posterior segments of the upper lobes and the apical segment of the lower lobes are most commonly affected. Complications include progressive cavity formation and endobronchial spread.

Extrathoracic Disease

Cervical lymphadenitis The most common extrathoracic manifestation of TB in children is cervical lymphadenitis. The cervical mass is usually painless and includes matted nodes with surrounding inflammation, resulting in a cold abscess when the caseous material liquefies. The overlying skin gets discolored and spontaneous drainage and sinus formation may follow. Usually, a single group of lymph nodes is involved and generalized lymphadenopathy goes against the diagnosis of TB.

In an endemic country, a lymph node mass more than 2 cm in a child that persists despite a course of broad spectrum antibiotics has a high likelihood of TB. Establishing a definitive diagnosis is

Figure 5 Paratracheal and perihilar lymph nodes

Figure 6 Tubercular pleural effusion (left)

preferable and can be done in a minimally invasive fashion using fine needle aspiration cytology (FNAC). The sensitivity of FNAC varies from 50% to 70% and a smear for acid-fast bacillus (AFB) staining must be done in addition to cytopathology to improve diagnostic sensitivity. If inconclusive, an open biopsy must be planned.

Tuberculous meningitis (TBM) (Also See Chapter 42.16) It is the most severe manifestation of childhood TB. Bacille Calmette-Guerin (BCG) vaccination provides some degree of protection (50-70%) against the severe forms of TB (miliary disease and TBM), but despite universal BCG vaccination in most TB endemic areas

severe disease manifestations still occur. TBM is most common in young children who frequently present with nonspecific symptoms—early diagnosis requires a high index of suspicion and is essential to ensure an optimal outcome. Symptoms of early disease include fever, listlessness, apathy, anorexia and/or failure to thrive and headache (in older children). As the disease progresses, convulsions and altered sensorium with or without neck stiffness and localizing neurological signs develop. The symptoms are due to the combined effects of raised intracranial pressure and cerebral vasculitis with brain ischemia/infarction. On CT or MRI scans, dense basal exudates and enlarged ventricles are the main findings.

Perinatal TB Newborn babies may acquire TB either congenitally or from their environment, and are at high risk of rapid disease progression. Congenital TB infection is acquired via the placenta or during birth by aspiration of infected amniotic fluid in which case primary lung involvement usually follows. This usually occurs when the mother develops TB during pregnancy, with hematogenous dissemination. Alternatively, the baby may inhale the bacillus after delivery (postnatal TB) if in close contact with an infectious adult.

Abdominal tuberculosis See Chapter 35.19.

DIAGNOSIS

The difficulty in confirming the diagnosis (needing multiple specimens other than sputum and a laboratory capable of performing culture), is due to the higher proportion of smear and culture-negative and extrapulmonary TB in young children, and the reluctance to collect specimens due to lack of training and/or awareness among healthcare workers.

The diagnosis of TB in children can be made on clinical and radiological grounds in the majority of cases, when bacteriological confirmation is not possible. Depending on the age of the child, site of disease, and available facilities, attempts can be made to obtain sputum, gastric aspirates, induced sputum, pleural or peritoneal fluid, CSF, nasopharyngeal aspirates, lymph node aspiration biopsy, or tissue biopsy and microbiologic confirmation increases with the number of samples. Invasive methods, such as bronchoalveolar lavage, bronchoscopic biopsy, or open lung biopsy may sometimes be required.

Children may be evaluated for TB when they fall sick and present for care (passive case finding), or as a result of contact investigation (active case finding).

Clinical Approach

A careful history including possible TB exposure in the wider family circle is important. Common symptoms include failure to thrive (deviation on growth chart) and reduced playfulness; low-grade persistent fever is less common. With airway involvement, the usual presenting symptom is a persistent nonremitting cough, unresponsive to antibiotics. There are many scoring systems available but none has been adequately validated; sensitivity and specificity is particularly poor in HIV-infected children. Diagnosis is based on a combination of clinical, radiological, and/or laboratory findings consistent with TB, together with epidemiological evidence of TB exposure or immunological evidence of *M. tuberculosis* infection [TST or interferon-gamma release assays (IGRAs)].

Imaging

Chest radiography is the most commonly performed and useful investigation. Both AP and lateral views should be taken; lateral views assist assessment of the mediastinum and hilar areas. However, pediatric radiographs must be interpreted properly as

hilar vasculature is often mistaken for lymph node enlargement. Ultrasound is useful to confirm pericardial or pleural effusions and abdominal lymphadenopathy, solid organ involvement or ascites. High-resolution computed tomography (CT) is very sensitive, but its use should be reserved for complicated intrathoracic cases due to high radiation exposure and cost. CT and MRI are useful for neurological involvement: MRI is more sensitive for detecting brainstem lesions or early perfusion defects in patients with TBM, and also provides better evaluation of the spine and soft tissues.

Laboratory Studies

Table 2 summarizes available diagnostic investigations. Sputum smear-microscopy is still the most widely available test, but has poor sensitivity in young children with paucibacillary disease who are unable to expectorate. The Xpert-MTB/RIF[®] assay is rapid and highly specific and using two sputum samples, it detects three times more cases than microscopy, and sensitivity is about 70% compared to culture. Immunological assays, the traditional TST and newer IGRAs fail to differentiate *M. tuberculosis* infection from TB disease. WHO recommends that IGRAs should not replace the TST for the detection of *M. tuberculosis* infection in low- or middle-income countries, although they provide similar information.

Expectorated sputum can be collected in children over 7–8 years of age, in younger children, gastric aspirates or lavage and induced sputa are preferred. **Table 3** provides an overview of specimen collection technique. The string test seems promising, although administration is difficult in young children who are unable to swallow the string containing capsule. Recently, stool has been suggested as a promising specimen for diagnosis in young children, but needs proper decontamination and adequate DNA extraction protocols. FNAC is very useful in children with a peripheral lymph node mass. The Union developed a pragmatic desk guide for TB diagnosis and management in resource-limited settings.

MANAGEMENT

Treatment of TB follows the basic principles of short-course therapy with a combination of bactericidal and sterilizing drugs and is similar to treatment of TB in adults. WHO recommends that children with uncomplicated disease, from settings with a low prevalence of INH resistance, can be treated with three drugs [INH, RIF and pyrazinamide (PZA)] during the 2-month intensive phase, followed by INH and RIF during the 4-month continuation phase. However, children with extensive and/or cavitary lung disease (implying a high organism load), or from settings with a high prevalence of INH resistance, should receive a fourth drug (ethambutol, which is safe in children of all ages within the recommended dosage range) during the 2-month intensive phase. Further, children with HIV infection or those living in an HIV prevalent region should receive four drugs. **Table 4** summarizes the mechanism of action, main adverse effects and recommended pediatric dosages of first-line TB drugs.

Drug resistance should be considered in children following documented contact with a patient with DR-TB, someone who died while on TB treatment without known drug susceptibility test results, is poorly adherent to therapy, or is a retreatment case. While data is limited, studies have shown that rates of drug resistance in children are generally similar to those in the adult population in the region.

All TB medications should preferably be given as directly observed therapy (DOT)—this can be by a health worker or parent. Proper counseling should be given to ensure compliance. In general, response to treatment is excellent with cure rates exceeding 90% in most settings. However, radiographic abnormalities especially hilar/mediastinal lymphadenopathy can persist and may take

Table 2 Summary of investigations to diagnose tuberculosis in children

Investigation	Uses	Strengths and limitations
Microbiological studies		
Microscopy	Diagnosis of TB	<i>Strengths:</i> Specificity high. Useful in all specimen types. Rapid (< 1 hour) detection. Low cost. <i>Limitations:</i> Sensitivity very low, especially in young children. Technician-dependent. Labor intensive. Unable to distinguish viable and dead bacilli
Culture	Diagnosis of TB; drug susceptibility testing	<i>Strengths:</i> Specificity high. <i>Limitations:</i> Sensitivity moderate to low in young children; slow turnaround time, need proper laboratory facilities
DNA detection (PCR) and CB-NAAT (Xpert MTB/Rif)		<i>Strengths:</i> Specificity high; Fully automated; Rapid turnaround. <i>Limitations:</i> Sensitivity moderate to low in young children; unable to distinguish viable from dead bacilli
Histopathological studies		
Stained tissue samples and fine needle aspiration cytology	Diagnosis of TB	Allows exclusion of other diagnoses (such as malignancy)
Immune-based studies		
TST; IGRA (e.g., Quantiferon Gold®)	Diagnosis of <i>M. tuberculosis</i> infection	Neither test can differentiate <i>M. tuberculosis</i> infection from TB disease; careful evaluation of discordant results <i>TST:</i> Requires a second visit after 48–72 hours, sensitivity lower in young and malnourished children <i>IGRAs:</i> Unaffected by BCG vaccination; single visit; reduced sensitivity in very young and/or immunocompromised children; collecting adequate volume of blood and indeterminate results problematic
Imaging		
Radiography CT and MRI Ultrasonography	Diagnosis of TB	Chest radiography (AP and lateral views) most common and useful; CT or MRI useful in uncertain or complicated cases and in CNS or bone and joint involvement; US useful to identify intra-abdominal/retroperitoneal lymphadenopathy or pleural/pericardial effusions, highly technician dependent

Abbreviations: CT, computed tomography; MRI, magnetic resonance imaging; US, ultrasound; CNS, central nervous system; BCG, Bacille Calmette-Guerin; TST, tuberculin skin test; IGRA, interferon-gamma release assays.

Table 3 Specimens for microbiologic investigations

Specimen collection method	Problems/Benefits	Potential clinical application
Sputum	Not feasible in very young children; assistance and supervision may improve the quality of the specimen	Routine sample to be collected in children > 7 years of age (all children who can produce a good quality specimen)
Induced sputum	Comparable yield to gastric aspirate; no age restriction; specialized technique, which requires nebulization and suction facilities; potential transmission risk	To be considered in the hospital setting on an in- or outpatient basis
Gastric aspirate	Unpleasant procedure, but not difficult to perform; requires fasting, can be done as outpatient procedure; sample collection advised on at least 2 consecutive days	Routine sample collected in young children who cannot produce a good quality sputum specimen
Nasopharyngeal aspiration	Less invasive than gastric aspirate; no fasting required; comparable yield to gastric aspirate	To be considered in primary health care clinics or on an outpatient basis.
String test	Less invasive than gastric aspirate; tolerated well in children > 4 years; bacteriologic yield, feasibility and ideal string/capsule need further investigation	Useful in children who can swallow the capsule, but cannot produce a good quality sputum specimen
Bronchoalveolar lavage	Extremely invasive	Only for use in patients who are intubated or who require diagnostic bronchoscopy
Stool	Culture not practical, high contamination rates, DNA extraction difficult, <i>M. tuberculosis</i> excretion well documented	Reasonable yield using Gene Xpert in young children
Urine	Not invasive; excretion of <i>M. tuberculosis</i> components, including transrenal DNA	Lipoarabinomannan assay has poor sensitivity; unreliable in children
Blood/Bone marrow	Good sample sources to consider in the case of probable disseminated TB	Useful for the confirmation of probable disseminated TB in hospitalized patients
Cerebrospinal fluid	Fairly invasive; bacteriologic yield low, Gene Xpert useful	To be considered if signs of tuberculosis meningitis
Fine needle aspiration biopsy (FNAB)	Minimally invasive using a fine 23 G needle; excellent bacteriologic yield including Gene Xpert, minimal side-effects	Procedure of choice in children with superficial lymphadenopathy

Table 4 Summary of first-line TB drugs and dosage recommendations in children

First-line drugs	Mode and mechanism of action	Main toxicities ¹	Daily dose mg/kg (range); [maximum dose] ²
Isoniazid (INH)	<i>Bactericidal</i> <ul style="list-style-type: none"> • Inhibits cell wall synthesis • Most potent early bactericidal activity offering the best protection to companion drugs • Contributes mainly by rapidly killing actively metabolizing extracellular bacilli, contributes to sterilization if given for a prolonged period 	Hepatitis; peripheral neuropathy	10 (7–15) [300 mg]
Rifampin (RIF)	<i>Bactericidal and sterilizing</i> <ul style="list-style-type: none"> • Inhibits RNA synthesis • Contributes by killing extracellular and slower growing intracellular bacilli, important contribution to sterilization 	Hepatitis; orange discoloration of secretions; drug-drug interactions	15 (10–20) [600 mg]
Pyrazinamide (PZA)	<i>Sterilizing</i> <ul style="list-style-type: none"> • Disrupts energy metabolism • Contributes by specifically killing bacilli that persist within the acidic centers of caseating granulomas. 	Hepatitis; arthralgia	35 (30–40) [2,000 mg]
Ethambutol (EMB)	<i>Bacteriostatic</i> <ul style="list-style-type: none"> • Inhibits cell wall synthesis • Contributes mainly by offering some additional protection against drug-resistant mutants 	Visual disturbance (acuity, color vision)	20 (15–25) [1,200 mg]
Suggested treatment regimens			
Disease category	Treatment regimen	Rationale	
Uncomplicated intrathoracic disease	INH, RIF, PZA (2-month intensive phase) INH, RIF (4-month continuation phase)	Organism load low, drug penetration good	
Extensive lung infiltrates and/or cavities, HIV co-infection, high baseline isoniazid resistance in community	Add EMB during 2-month intensive phase	Organism load high, drug penetration good, pre-existing drug resistance rates high	
Tuberculous meningitis (TBM) ³	Add fourth drug—at least during 2-month intensive phase. Prolong continuation phase to 10 months (WHO recommendation) Add steroids for 1 month	Organism load low, drug penetration variable, risk of severe immunomediated sequelae	
Severe airway compression	3 or 4 drug regimen depending on extent of lung infiltration/cavities Consider adding steroids for 1 month	Organism and drug penetration variable, ⁴ inflammation may worsen airway compression	
Recent exposure/infection	Preventive therapy	Organism load very low, drug penetration good	
No active disease	INH (6–9 months) INH, RIF (3 months)		

¹Hypersensitivity reactions and drug rashes may occur with any drug; ²WHO dosage recommendations for children; ³Recommendations around fourth drug and duration of therapy vary; ⁴Drug penetration into large cold abscesses may be limited, requiring surgical drainage

Source: Adapted from Perez-Velez CM, Marais BJ. Tuberculosis in children. *N Engl J Med*. 2012;367:348–61.

years to regress. **Flow charts 1A and B** shows the RNTCP algorithm for the diagnosis of TB in children. Poor clinical response to adherent treatment requires critical re-evaluation of the diagnosis, including other infections, immune reconstitution inflammatory syndrome (IRIS) and drug resistance. Good treatment outcomes can be achieved even in children with DR-TB if diagnosed on time and managed appropriately. In children with disseminated disease or TB affecting the CNS or bones and joints, treatment should be extended up to 12 months.

In HIV-infected children, immune recovery following ART initiation may unmask existing subclinical disease or induce paradoxical deterioration despite adequate TB treatment. The IRIS does not indicate treatment failure and treatment should usually not be interrupted; severe cases may require a course of corticosteroids. In order to reduce mortality due to TB, ART is best initiated within 8 weeks of starting TB treatment, and within 2–4 weeks in the severely immunocompromised. The only

exception for stopping or delaying ART would be patients with central nervous system TB, where IRIS can be dangerous. With HIV-associated TB, treatment should be daily.

DRUG-RESISTANT TUBERCULOSIS

Resistance to anti-tuberculosis (anti-TB) drugs is caused by spontaneous chromosomal mutations, present in low numbers in mycobacterial populations. An anti-TB drug suppresses replication of susceptible bacilli but allows DR mutants to replicate. Selection pressure imposed by an anti-TB drug on a population of *M. tuberculosis* results in a decline of drug-susceptible bacilli and advantageous reproduction of DR mutants, which is known as the *fall and rise phenomenon*. Consequently, DR mutants may outnumber drug-susceptible bacilli and become the dominant bacilli. This is acquired resistance, implying that resistance emerges during anti-TB treatment. An inappropriate drug regimen, use

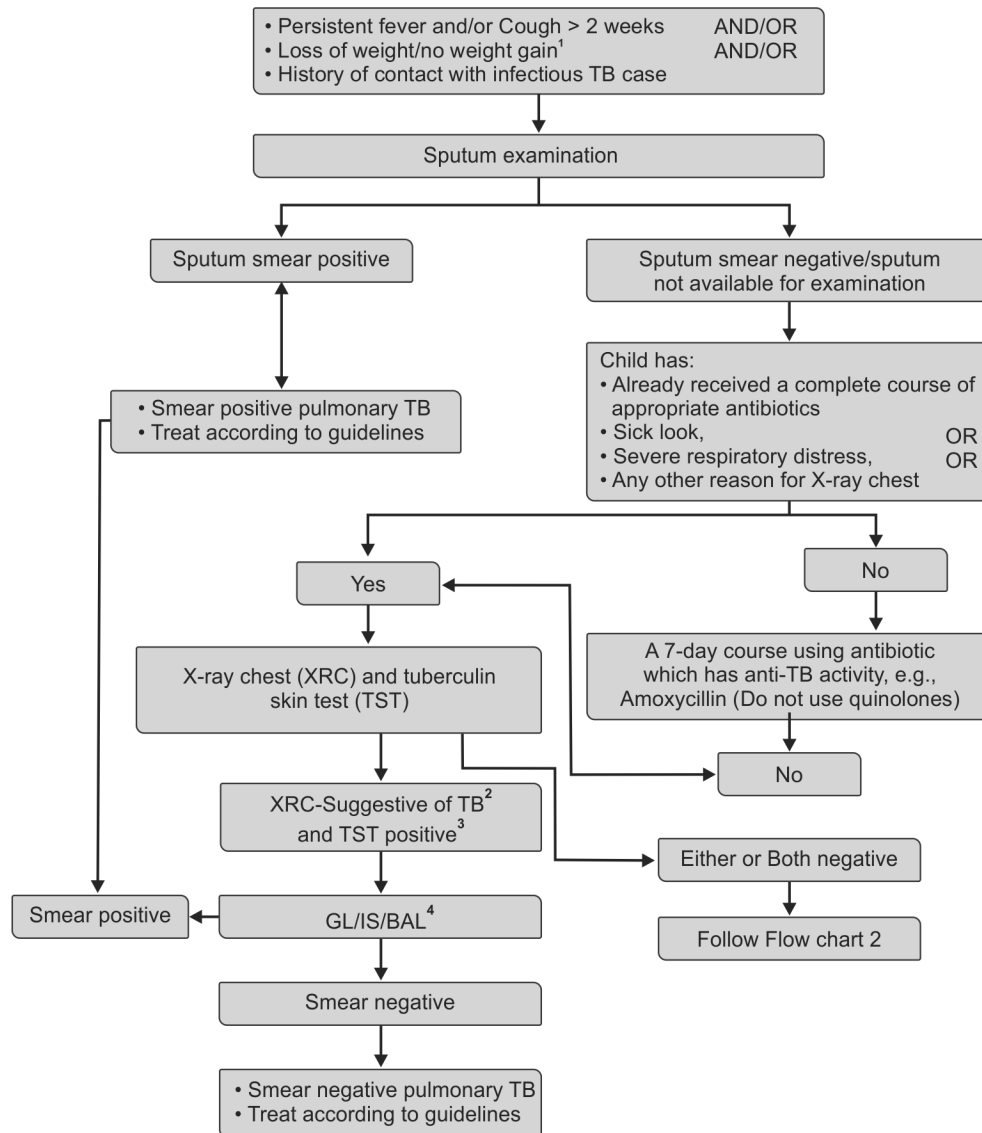

of a lower-than-recommended dosage, inferior drug quality and poor adherence to treatment are commonly associated with the emergence of drug resistance in individual patients.

Primary resistance in TB refers to patients infected with *M. tuberculosis* that is resistant to anti-TB drugs from the outset, prior to anti-TB treatment. DR-TB in children is usually due to transmission of resistant strains from an infected source (primary). Mono drug resistance is defined as resistance to one anti-TB drug, while poly drug resistance refers to resistance to two or more drugs. *Multidrug resistance* tuberculosis (MDR-TB) is a specific form of poly drug resistance defined as resistance to at least H and R.

Extensively drug-resistant TB (XDR-TB) is a special form of MDR-TB defined as resistance to at least H and R with further resistance to a fluoroquinolone and a second-line injectable agent (amikacin, kanamycin or capreomycin). The molecular basis of resistance to INH and RIF (and some other drugs) is now understood (**Table 5**).

The prevalence of drug-resistant TB in children has not been well-documented, but in general, the rates reflect the adult prevalence in that region. A recent modeling exercise estimated that around 999 792 (95% CI 937 877–1 055 414) children developed TB disease in 2010, of whom 31 948 (25 594–38 663) had multidrug-resistant disease. In India, MDR-TB in children has been found in

Flow chart 1A RNTCP diagnostic algorithm for pediatric tuberculosis

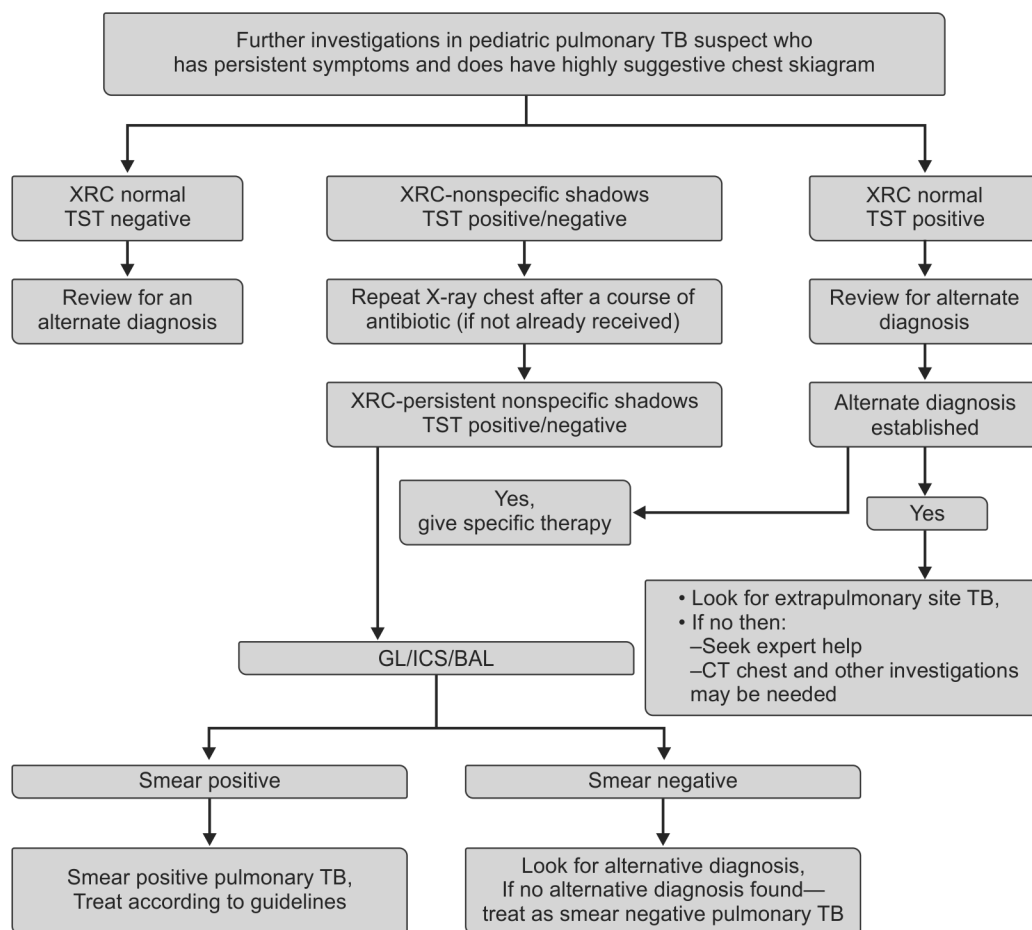

¹History of unexplained weight loss or no weight gain in past 3 months; loss of weight defined as loss of more than 5% body weight as compared to highest weight recorded in last 3 months

²Radiological changes highly suggestive of TB are Hilar/paratracheal lymphadenitis with or without parenchymal lesion, miliary TB fibrocavitary pneumonia

³If the radiological picture is highly suggestive of TB, then proceed to do further investigations irrespective of the TST result as the sensitivity of the test is not 100%

⁴All efforts including gastric lavage (GL)/induced sputum (IS) or bronchoalveolar lavage (BAL) should be made to look for acid-fast bacilli (AFB) depending upon the facilities

All efforts including gastric lavage (GL)/induced sputum (IS) or bronchoalveolar lavage (BAL) should be made to look for acid-fast bacilli (AFB) or for M to rapid culture or Gene Xpert[®] wherever facilities are available

Flow chart 1B RNTCP diagnostic algorithm for pediatric TB

Abbreviations: TB, tuberculosis; XRC, X-ray chest; TST, tuberculin skin test.

Table 5 Genetic sites for drug resistance in tuberculosis

Drug	Target	Gene
Isoniazid	Catalase-peroxidase enzyme	Kat G
Isoniazid-ethionamide	Mycolic acid synthesis	Inh A
Rifampin	RNA polymerase	Rpo B
Streptomycin	Ribosomal S12 protein 16S rRNA	Rpsl rrs
Quinolones	DNA gyrase	gyrA
Pyrazinamide	Pyrazinamidase-nicotinamidase	pncA
Ethambutol	Arabinosyl transferase	embcAB
PAS	Thymidylate synthase thy A	ThyA
Kanamycin	Ribosomal RNA	rrs

Abbreviations: PAS, para-aminosalicylate sodium.

Source: Adapted from Ormerod LP. Multidrug-resistant tuberculosis (MDR-TB): epidemiology, prevention and treatment. Br Med Bull. 2005;73-74(1):17-24.

3.5% in Chennai and 5% in Mumbai among all children with culture confirmed disease. A history of contact with an adult with MDR-TB is a critical pointer. Since only a small proportion of TB in children is culture-confirmed, drug resistance should be suspected whenever the child has been in contact with an adult with confirmed MDR-

TB or one who died or defaulted while on treatment, as well as a child who is failing or deteriorating on treatment. A diagnosis of *probable MDR-TB* can be made and the child started on treatment.

The principles of treatment regimen design for children are the same as for adults with MDR-TB. One major difference for children is that their treatment is often empiric and based on the drug susceptibility pattern of the source case, if available, or on past history of treatment. Depending on country guidelines, the regimen used is either individually constructed or a standardized one, such as the category IV regimen recommended by WHO.

The basic principles are the following:

- Use any first-line medication to which susceptibility is documented or likely (high-dose INH could be included routinely, unless high-level INH resistance or Kat-G mutation is documented).
- Use of at least four second-line drugs to which the strain is likely to be sensitive; one of these agents should be an injectable, one should be a fluoroquinolone, and PZA should be continued.
- All doses should be given using DOT to ensure that patients adhere to treatment.
- Treatment duration should be for 18–24 months, at least 12 months after the last positive culture/smear with minimal disease or 18 months with extensive (lung cavities or wide-spread parenchymal involvement) disease.

Table 6 shows the five groups of drugs placed by WHO used to treat DR-TB in children.

PREVENTION

Transmission within healthcare facilities is a possibility, especially when dealing with immunocompromised children and good ventilation is important in inpatient and outpatient facilities. Although BCG vaccination reduces the risk of disseminated (miliary) disease and TBM in young children, it offers no consistent protection against TB beyond the first few years of life. In HIV-infected children, BCG vaccination is contraindicated due to the risk of disseminated BCG disease. However, it is still given soon after birth in India, as population prevalence of HIV is very low and the benefits outweigh the risks. The development of a safe and effective vaccine remains a top global health research priority.

Isoniazid preventive therapy (IPT) for 6–9 months has been shown to provide excellent protection against TB disease, and has

been recommended by WHO for many years. Contact screening of family members living with an infectious patient and IPT for children under 6 years is a policy of RNTCP, but implementation is poor. Parents need proper counseling and advice in order to comply with giving drugs to an otherwise well child. Alternate regimens include INH and RIF for 3 months, which provides equivalent efficacy and improved adherence compared to 9 months of INH. A regimen of 12 doses of weekly rifapentine and INH was efficacious in adults, and is being studied in children.

All RIF and rifapentine-containing regimens interact with protease inhibitor-containing ART; this is less with rifabutin, but its use in preventive therapy regimens has not been evaluated. For children exposed to MDR-TB, there is no preventive therapy regimen that has been tested in clinical trials and the best option may be to keep such children under close observation. A regimen containing high dose INH, levofloxacin and ethambutol has been tried in South Africa to prevent MDR-TB in child contacts, but is not routinely recommended.

Table 6 Drugs used to treat TB in children

Group and Group name	Drugs	Dosage* (mg/kg)	Adverse events
1. First-line oral agents	Isoniazid	10–15	Hepatitis, peripheral neuropathy
	Rifampin	10–20	Hepatitis, discoloration of secretions
	Ethambutol	15–25 (DR-TB: 20–25)	Optic neuritis
	Pyrazinamide	30–40	Hepatitis, arthritis
2. Injectable agents	Kanamycin	15–30	Ototoxicity, nephrotoxicity
	Amikacin	15–22.5	As above
	Capreomycin	15–30	As above
	Streptomycin	15–20	As above
3. Fluoroquinolones	Ofloxacin	15–20	Sleep disturbance, gastrointestinal disturbance, arthritis, peripheral neuropathy
	Ciprofloxacin	20 twice daily	As above
	Levofloxacin	7.5–10 ⁺	As above
	Moxifloxacin	7.5–10	As above but including prolonged QT syndrome
4. Oral bacteriostatic second-line agents	Ethionamide	15–20	Gastrointestinal disturbance, metallic taste, hypothyroidism
	Prothionamide	15–20	As above
	Cycloserine	15–20	Neurological and psychological effects
	Terizidone	15–20	As above
	Para-aminosalicylic acid	150	Gastrointestinal intolerance, hypothyroidism, hepatitis
5. Agents with unclear efficacy	Clofazimine	3–5	Skin discoloration, xerosis, abdominal pain
	Linezolid	10 ⁺	Diarrhea, headache, nausea, myelosuppression, neurotoxicity, lactic acidosis, pancreatitis, and optic neuropathy
	Amoxicillin-clavulanic acid	10–15 (amoxicillin component) three times a day	Gastrointestinal intolerance, hypersensitivity reaction, seizures, liver and renal dysfunction
	Imipenem/cilastatin		As above
	Thiacetazone	2.5	Stevens Johnson syndrome in HIV-infected patients, gastrointestinal intolerance, hepatitis, skin reactions
	High dose isoniazid	15–20	Hepatitis, peripheral neuropathy, neurological and psychological effects
	Clarithromycin	7.5–15 twice daily	Gastrointestinal intolerance, rash hepatitis, prolonged QT syndrome, ventricular arrhythmias

Abbreviation: HIV, human immunodeficiency virus.

* Daily unless otherwise specified; + The stated doses is advised to be given twice a day for children less than 5 years

IN A NUTSHELL

1. The majority of children are sputum microscopy smear and culture negative, and hence the true burden of childhood TB is not known.
2. Human immunodeficiency virus infection increases susceptibility to infection with *Mycobacterium tuberculosis*, the risk of progression from infection to TB disease as well as reactivation of latent TB.
3. The youngest of all children have the most rapid disease progression and severe types of disease. Adult-type disease is common during adolescence, but can occur from 8 years onward.
4. The most common extrathoracic manifestation of TB in children is cervical lymphadenitis.
5. Bacteriologic confirmation of diagnosis needs multiple specimens other than sputum (gastric aspirate or induced sputum) and a laboratory capable of performing culture.
6. Diagnosis is based on a combination of clinical, radiological, and/or laboratory findings consistent with TB, together with epidemiological evidence of TB exposure or immunological evidence of *M. tuberculosis* infection (TST, interferon gamma release assays).
7. The Xpert-MTB/RIF[®] assay is rapid and highly specific and using two sputum samples, it detects three times more cases than microscopy, and sensitivity is about 70% compared to culture.
8. Treatment of TB follows the basic principles of short-course therapy with a combination of bactericidal and sterilizing drugs and is similar to treatment of TB in adults (6 months standard duration).
9. Drug resistance should be considered in children following documented contact with a patient with drug-resistant TB, someone who died while on TB treatment without known drug susceptibility test results, is poorly adherent to therapy, or is a re-treatment case.
10. Multidrug-resistant tuberculosis is treated with a 24-month regimen with second line drugs. Good treatment outcomes can be achieved even in children with DR-TB if diagnosed on time and managed appropriately.

Chapter 30.3

Atypical Mycobacterial Infections

C Padmapriyadarsini, Soumya Swaminathan

Atypical mycobacteria are also called nontuberculosis mycobacteria (NTM) or mycobacteria other than tuberculosis (MOTT). These are widely distributed in our environment. They have been isolated from soil, dust, biofilms and water—both natural as well as drinking water; the species, however, may differ from one geographical area to another. Exposure to these reservoirs is thought to be the source of human infection, though the specific source of infection cannot be usually identified.

CLASSIFICATION

Nontuberculosis mycobacteria are broadly divided into two main groups: Slow growers and rapid growers, according to their rate of growth on subculture. Currently, there are more than 140 identified NTM species and many of these have been reported to cause disease in both immunocompetent and immunocompromised individuals (Table 1).

EPIDEMIOLOGY

Studies across the world have reported an increase in the incidence or prevalence of NTM infection. The increase in the rate of NTM infection was usually associated with a decline in the rate of tuberculosis. The reasons for the increase in incidence and prevalence of NTMs include increased awareness of the disease as well as improved diagnostic techniques.

In India, till recently, culture was not a routine part of the diagnostic algorithm for tuberculosis (TB) and hence it is difficult to predict the exact magnitude of NTM in our country. Moreover, *M. tuberculosis* is much more common as a pathogen than NTM. Studies from various parts of the country have reported an NTM prevalence varying from 1–28% among chest symptomatics. With emergence of human immunodeficiency disease, a few studies have shown the presence of NTM in HIV infected patients in India.

Table 1 Classification of nontuberculosis mycobacteria

Slowly growing NTM	Rapidly growing NTM
Photochromogens—	<i>M. abscessus</i>
<i>M. kansasii</i>	<i>M. holsaticum</i>
<i>M. marinum</i>	<i>M. bollettii</i>
<i>M. simiae</i>	<i>M. chelonae</i>
Scotochromogens—	<i>M. fortuitum</i>
<i>M. avium</i>	<i>M. goodii</i>
<i>M. gordonae</i>	<i>M. massiliense</i>
<i>M. scrofulaceum</i>	<i>M. mucogenicum</i>
Nonchromogens—	<i>M. smegmatis</i>
<i>M. avium intracellulare</i>	<i>M. septicum</i>
<i>M. malmoense</i>	
<i>M. terrae</i>	
<i>M. ulcerans</i>	
<i>M. xenopi</i>	

PATHOGENESIS

Macrophages that phagocytose mycobacteria produce interleukin-12 (IL-12), which in turn, up regulates interferon-gamma (IFN- γ) production by lymphocytes. IFN- γ , in turn activates neutrophils and macrophages to kill the intracellular mycobacteria. This cycle between IFN- γ and IL-12 is critical for the control of mycobacterial infections. Specific mutations in the different genes responsible for synthesis of IFN- γ and IL-12 or in their receptors have been associated with disseminated NTM disease. Further, mutation in genes associated with synthesis of transducer and activator of transcription 1 (STAT1) have also been involved with NTM infection.

In children with human immunodeficiency virus infection, NTM disease occurs when the CD4 T lymphocytes have declined to less than 50 cells/mm³. Similarly, other conditions where cell-mediated immunity is depressed (e.g., long-term steroid treatment, anticancer chemotherapy, etc.) also predispose to NTM infection. An association has also been found between bronchiectasis, nodular pulmonary NTM infections and a particular body habitus (e.g., pectus excavatum, scoliosis, mitral valve prolapse). These phenotypic characteristic may represent markers for specific genotypes that affect both body morphology and NTM infection susceptibility.

Transmission

There is no evidence of animal-to-animal or human-to-human transmission of NTM. Human disease is presumably acquired from environmental exposure, though a specific source may be difficult to identify. The various species also vary greatly in their ability to cause disease. Portal of entry of NTM among children is not known, but predominance of cervical lymphadenitis suggests the oral route. It may be related to eruption of primary teeth, exposure to environmental mycobacteria in playing grounds, etc. Recently, a few cases of NTM wound infections have been described, especially after laparoscopic surgery.

CLINICAL PRESENTATION

Nontuberculosis mycobacteria cause four main types of diseases: (1) lymphadenitis, (2) chronic pulmonary, (3) postinoculation and (4) disseminated disease.

Lymphadenitis

This is the most common form of NTM disease in children. Occurring insidiously, most frequently in children between 1 year and 5 years of age, cervical lymph nodes are most commonly affected. Submandibular, submaxillary or preauricular lymph nodes may also be involved besides cervical lymphadenitis. The involved lymph nodes are generally unilateral, nontender and unresponsive to conventional antibiotics. Nodes may enlarge rapidly and even rupture to form sinus or fistula resulting in prolonged local drainage. Spontaneous regression can occur. Other lymph node groups like mediastinal lymph nodes may also be involved.

Superficial lymphadenitis, especially cervical lymphadenitis, in children is caused mostly by *M. avium* complex, *M. scrofulaceum* or *M. malmoense* though *M. tuberculosis* is still a more common cause of lymphadenitis in TB-endemic countries. In a clinical trial of TB lymphadenitis in children, Jawahar et al. found *M. tuberculosis* in more than 99% of patients. Unlike TB lymphadenitis, with NTM lymphadenitis there is typically no history of exposure to TB, screening tuberculin skin tests of the child and family members are usually negative and chest radiograph is normal.

No risk factors predisposing to NTM cervical lymphadenitis in children have been identified, but children with Bacille Calmette-Guerin (BCG) immunization have a reduced risk of NTM cervical lymphadenitis.

Chronic Pulmonary Disease

This is the most common form of NTM disease in adults—middle-aged men are more frequently affected. Patients present with chronic or recurrent productive cough, fatigue, malaise, dyspnea, fever, chest pain, hemoptysis and weight loss. Auscultation may reveal crepitations and wheeze in the lung fields. Predisposing factors for this form of NTM disease usually includes local lung lesions like old tubercular cavities, chronic obstructive pulmonary disease (COPD), bronchiectasis, and cystic fibrosis.

Postinoculation

This form of NTM disease can occur following injections as post-injection abscesses, following laparoscopic surgeries at the port site (surgical inoculation), keratitis, through cuts and abrasions, during water games like swimming or attending to fish tanks, etc. Post injection abscesses usually develop due to use of contaminated multidose vaccines, 1–12 months after vaccination and tend to be localized. Buruli ulcer caused by *M. ulcerans* can present as single firm painless subcutaneous nodule on the limbs. These nodules may ulcerate and either become inactive and heal by scarring or disseminate to cause indurated plaques covering the entire limb.

Disseminated Disease

This was commonly reported in patients with AIDS in the pre-ART era. Usually infection with *M. avium complex* occurred in children with congenital immunodeficiencies or *M. chelonae* in renal transplant recipients. But with emergence of HIV pandemic, disseminated NTM with *M. avium* or *M. genavense* was reported in around 30–40% of patients with AIDS. Children present with nonspecific symptoms like fever, weight loss, night sweats or anemia and the diagnosis is made by blood culture or lymph node or bone marrow biopsies.

DIAGNOSIS

Infection with NTM should be suspected in children with TB-like signs and symptoms, in whom initial antitubercular treatment or antibiotics have not produced the desired response. This should be supported by repeated isolation of the same NTM species from sputum, bronchoalveolar lavage or from the local lesion like lymph node or ulcers. The American Thoracic Society (ATS) recommends a combination of both clinical and microbiological criteria to diagnose pulmonary NTM disease.

Clinical (Both Required)

- Pulmonary symptoms, nodular or cavitary opacity in chest radiograph or HRCT scan that shows multifocal bronchiectasis with multiple small nodules and
- Appropriate exclusion of other diagnosis.

Microbiological

- Positive culture results from at least 2 separate expectorated samples or...
- Positive culture from at least one bronchial wash/lavage or...
- Transbronchial or other lung biopsy with mycobacterial histological feature [granulomatous inflammation or acid-fast bacilli (AFB)] and positive culture for NTM.

- Patients who are suspected of having NTM lung disease but do not meet diagnostic criteria should be followed until firm diagnosis is established or excluded.

There are no reference standards for laboratory diagnosis of NTM infection. Diagnosis is usually made on a combination of findings.

Culture of Nontuberculosis Mycobacteria

A definite diagnosis of NTM lymphadenitis is made by recovery of the causative organism from lymph node cultures. Cultures should include both solid and broth media for detection of mycobacteria and a semi quantitative colony count reporting is recommended. Most NTM grow within 2–3 weeks of subculture, while the rapid growers appear within 7 days of subculture. Failure of the lymph node culture to yield *M. tuberculosis* provides stronger presumptive evidence for the diagnosis of NTM lymphadenitis. However, the disease characteristics do not differ between children with positive culture from those without a positive culture.

Diagnosis of pulmonary NTM disease can be made by isolation and identification of causative organism in the sputum or the bronchoscopic specimens.

Identification of Nontuberculosis Mycobacteria Species

Currently there are multiple techniques for NTM species identification, including phenotypic, chemotaxonomy, nucleic acid probes, polymerase chain reaction and other amplification methods, high-performance liquid chromatography (HPLC) and nucleic acid sequencing. HPLC, which analyzes the chromatographic profile of the mycolic acids, extracted from the bacterial cell wall, speciates a large number of NTM. Identification of mycobacteria by sequencing of the 16S ribosomal RNA, which is highly conserved so that 1% or greater differences in this gene sequence can define an NTM species more accurately. DNA fingerprinting techniques have also been tried to identify the strains of NTM. In India, information on molecular types of NTM is scanty.

Sensitivity Profile

Drug susceptibility profile of NTM is usually very different from *M. tuberculosis*. Rapidly growing NTMs are usually resistant to rifampicin and isoniazid while they are sensitive to drugs like new generation macrolides and cephalosporin. In children with NTM lymphadenitis, besides negative tuberculin test and normal chest X-ray, the organisms will be resistant to antitubercular drugs.

Histopathological Examination

The diagnosis of NTM lymphadenitis is based on the histopathological appearance of the lymph node showing caseating granulomas with or without AFB. Histopathology is a useful method to diagnose *Mycobacterium avium complex* (MAC) infections of the lymph nodes especially when it is confirmed with an *in situ* method like antigen detection or gene probe.

Imaging Techniques

Imaging of the head and neck in immunocompetent children, using computed tomography (CT) or magnetic resonance imaging (MRI) scan would reveal asymmetric adenopathy with contiguous low-density ring-enhancing masses, similar to TB lymphadenopathy. Inflammatory stranding of the subcutaneous fat may also be seen. In case of pulmonary NTM disease, plain chest radiograph or high resolution computed tomography (HRCT) would demonstrate the characteristic abnormality of nodular/bronchiectatic NTM lung disease. There are no diagnostically reliable clinical and radiological differences between NTM lung disease and TB and, diagnosis depends on the isolation and identification of causative organism.

Diagnostic Skin Testing

Testing can be done with purified protein derivative (PPD) of *M. avium* (PPD-A), *M. scrofulaceum* (PPD-S) or *M. kansasii* (PPD-K) in addition to *M. tb* (PPD-B) that often shows cross-reactivity and culture and cytological/histological examination of aspirated or biopsy specimen. Skin testing is cheap and easy to perform. However, interpretation of skin test results is not accurate as there is cross reactivity between mycobacterial antigens.

Other Biomarkers

Cytokine/Chemokine signature of IL-5, IL-9, IL-13 and IL-17 have been identified as immunological biosignature to differentiate exposure to *M. avium* and *M. kansasii* in children from latent TB infection in areas where both TB and NTM are endemic, as in India.

TREATMENT

Making the diagnosis of NTM disease does not, per se, necessitate treatment. Treatment depends on the site and severity of the infection, the presence of predisposing condition, such as congenital or acquired immunodeficiency and the virulence of the mycobacterium species. The decision to treat should also be based on potential risk and benefit of therapy for individual patients.

All patients should receive long-term antimycobacterial therapy with double or triple drug regimens. These include various combinations of clarithromycin, ethambutol, rifabutin, rifampin, clofazimine, and azithromycin (**Table 2**). Skin lesions may be cured by excision, curettage or drainage. Surgical excision, when technically possible, is used to treat lymphadenitis or localized pulmonary nodules.

Treatment of Lymphadenitis

There is a lack of consensus about optimal treatment of NTM infection in otherwise healthy children. Spontaneous regression

may occur in a proportion of cases while chemotherapy, surgery or a combination of both may be required in others. Excisional surgery without chemotherapy is the recommended treatment for children with NTM cervical lymphadenitis, including those with disease caused by *M. avium complex* and *M. scrofulaceum*. Success rate with surgery is approximately 95%. Benefits of complete surgical excision include: a greater chance of isolating the causative organism; higher cure rates; faster healing times; less need for repeat surgical interventions and improved esthetic results. If surgical excision is not considered feasible, antimicrobial therapy may be considered for some patients. For children with recurrent disease, a second surgical procedure is usually performed.

An alternative for recurrent disease or for children in whom surgical risk is high (e.g., risk of facial nerve involvement with preauricular nodes) is chemotherapy, with one of the macrolides like clarithromycin showing some benefit. Cure with medical management alone generally requires prolonged antimicrobial regimens. Drug treatment is directed against MAC unless a different mycobacterial species has been isolated. Therapy of 3–6 months with clarithromycin or azithromycin combined with ethambutol or rifampin may be beneficial for those patients with incomplete surgical excision due to disease near the facial nerve or with recurrent disease as surgery may be associated with complications like damage to facial nerve branches when submandibular nodes are involved.

PROPHYLAXIS

Chemoprophylaxis with antimycobacterial drugs, such as rifabutin, has been recommended as primary prophylaxis in western countries for AIDS patients. However, we lack information on the role of chemoprophylaxis in children with HIV/AIDS in India.

Table 2 Treatment schedule of common nontuberculous mycobacterial species in India

Species	Regimen with dose	Duration and rhythm of treatment	Alternative regimen/Follow-up monitoring
<i>Mycobacterium avium</i> complex	Clarithromycin* 7.5 mg/kg (max 500 mg) BD + rifampicin 10 mg/kg (max 600 mg) OD + ethambutol 15 mg/kg (max 1.5 g) OD orally	Treatment will be daily for a minimum of 18 months or until they have been culture negative for a period of 12 months	Azithromycin (10 mg/kg—max 500 mg) OD orally instead of clarithromycin or rifabutin** (150–300 mg) instead of rifampicin
<i>Mycobacterium abscessus</i>	Clarithromycin 7.5 mg/kg (max 500 mg) BD orally + amikacin IV 30 mg/kg OD + ceftioxin (max 12 g/day) (or imipenem)	3-week intensive phase followed by a prolonged continuation phase, is recommended as first line therapy Surgical resection	Full blood count and the patient's renal and hepatic function must be checked prior to initiating treatment Renal and liver function should be checked at 12 weekly intervals
<i>Mycobacterium kansasii</i>	Isoniazid 5 mg/kg/day; (max 300 mg) + rifampicin 10 mg/kg/day (max 600 mg) + ethambutol 15 mg/kg (max 1.5 g) od orally	Daily for 12 months of negative sputum culture while on therapy	Clarithromycin, rifabutin and ethambutol can be used as alternative regimen
<i>Mycobacterium fortuitum</i>	Clarithromycin + Doxycycline + TMP-SFX or levofloxacin	12 months of negative sputum culture while on therapy	Avoid minocycline, doxycycline and tigecycline in patients less than 12 years of age
<i>Mycobacterium terrae</i>	Optimal therapy has not been established. Suggests use of a macrolide + ethambutol or other agent based on in vitro susceptibility test		
<i>Mycobacterium chelonae</i>	Optimal therapy is still unknown. Suggested regimen including clarithromycin with a second agent (based on in vitro susceptibility) for 12 months of negative sputum cultures		
<i>Mycobacterium scrofulaceum</i>	Susceptibility data are lacking and standard treatment regimens is still controversial		

*The superiority of clarithromycin over azithromycin not demonstrated in trials.

**Most experts recommend rifampicin because of frequent adverse events with rifabutin.

IN A NUTSHELL

1. Atypical mycobacteria can affect both immunocompromised as well as immunocompetent individuals.
2. There is no evidence of animal-to-animal or human-to-human transmission of NTM. Human disease is presumably acquired from environmental exposure, though a specific source may be difficult to identify.
3. Infection with NTM should be suspected in children with TB-like signs and symptoms, in whom initial antitubercular treatment or antibiotics have not produced the desired response.
4. Cervical lymphadenitis is the most common form of NTM disease in children.
5. Making the diagnosis of NTM disease does not, per se, necessitate treatment. Treatment depends on the site and severity of the infection, virulence of the mycobacterium species and should also be based on potential risk and benefit of therapy for individual patients.

Chapter 30.4

Leprosy

Rajeshwar Dayal, Manoj Kumar Singh

Leprosy, also known as Hansen disease, is a chronic infection caused by the bacteria *Mycobacterium leprae*. It particularly affects peripheral nerves, skin, and mucous membranes in the cooler parts of the body, such as the upper respiratory tract, anterior chamber of the eye, and the testes.

EPIDEMIOLOGY

According to WHO, out of a total 232,857 registered cases of leprosy in the world in 2012, 125,171 (9.82% children) were residing in India. The prevalence rate decreased in last decade globally from 1.6/10,000 population in 1997 to 0.34/10,000 population in 2012.

Leprosy is widely prevalent in India. After introduction of MDT the total number of registered cases of leprosy came down to less than 0.1 million (prevalence rate of 0.66/10,000 population) in 2012 from 0.5 million (prevalence rate of 6.7/10,000 population) in 1997. The total number of new cases detected during 2012 in India was 166,445; of these, about 10% were children below 15 years of age.

ETIOLOGY

Leprosy is caused by *M. leprae* which is an acid-fast, nonsporing bacilli, and occurs both intracellularly as well as extracellularly. In stained smear it lies singly, as rods or in clumps called globi (Fig. 1). They have affinity for Schwann cells and cells of reticuloendothelial system. The bacillus cannot be grown in any artificial media. *M. leprae* does not produce any toxin and is well adapted to reside within macrophages, yet it may survive outside the body for months.

MODE OF TRANSMISSION

The only source of infection is the infected human being. The capacity of multibacillary leprosy patients to infect is 4–11 times that of patients with paucibacillary leprosy. The mode of transmission of leprosy has not been established with certainty.

Figure 1 Smear microscopy by Ziehl-Neelsen staining

Direct Transmission

For direct transmission, a prolonged and close contact is required. An intrafamilial contact with a patient is more risky than an extra-familial one. Untreated, lepromatous patients discharge as many as 100 million bacilli from their nasal secretions every day. These bacilli remain viable outside the human body for several days. Inhalation of these droplets is now regarded as the most common mode of entry of bacilli into contact person. After inhalation, these inhaled bacilli enter the respiratory system from where they are disseminated by blood to skin and peripheral nerves. Bacilli may also be transmitted by insect vectors, tattooing needles, or by ingestion of infected breastmilk. Through this abraded skin, the droplets laden with leprosy bacilli enter through the epidermis into the dermis.

Indirect Transmission

M. leprae remains viable for several days outside the human body. Occasionally, bacilli may be transmitted from person to person by close contact between an infectious patients and healthy but susceptible person. This contact may be direct or indirect (e.g., contact with soil and fomites such as contaminated clothes and linen).

CLINICAL MANIFESTATIONS

Incubation Period

Owing to the extremely slow dividing time of *M. leprae* (once every 2 weeks) the incubation period ranges from 6 months to more than 40 years and averages 2–5 years.

Clinical Features

Leprosy is primarily a granulomatous disease of the peripheral nerves and mucosa of the upper respiratory tract; skin lesions are the primary external sign. Left untreated, leprosy can be progressive, causing permanent damage to the skin, nerves, limbs and eyes. The age group most commonly affected is 5–14 years, though in very high endemic countries, prevalence in age groups 0–4 years is also significant. The early signs include:

- A hypopigmented patch in the skin, present for a long duration, nonirritating with loss of sensation to touch, pain and temperature
- Thickening of the skin, more red and shiny in appearance than surrounding parts; this is more prominent on face and hands
- Loss of sensation, numbness, feeling of pins and needles or crawling of ants, tingling sensation in any part of body
- Appearance of spontaneous blisters and ulcers, especially in the fingers.

CLASSIFICATION

Leprosy is classified into several types based on the bacterial load present in the lesions, the extent of skin and nerve involvement and based on the presence of deformities. Several types of classification exist like Madrid classification, Ridley and Jopling classification Indian classification, WHO classification, and Field Worker's Classification. According to the classification (1981) laid down by Indian Leprosy Association (*Hind Kusth Nivaran*), the cases are categorized into five broad groups *viz.*, indeterminate, borderline, tuberculoid, lepromatous and polyneuritic.

Indeterminate Leprosy

This type is seen in only 10–20% of infected individuals and is earliest detectable form of leprosy. This is characterized by presence of one or two vague hypopigmented macules and definite sensory impairment. The macule is of 2–4 cm in diameter, with

poorly defined border without any erythema or induration. The lesions are bacteriologically negative.

Tuberculoid Leprosy

Tuberculoid leprosy (TT) denotes those cases with single or few well-defined, hypopigmented, erythematous or copper-colored patches, and are anesthetic. The entire patch or only its margin is raised above the level of the surrounding skin. Initially, a single nerve trunk related to the lesions is affected. The nerve trunk becomes enlarged, hard, tender and later may form a nerve abscess. In this form, lepromin test is positive and there is absence of bacilli in skin smear. On biopsy, foci of lymphocyte, epithelioid cells and Langhans giant cells are seen. This form of leprosy is the most common, especially in children and is relatively benign and stable with a good prognosis.

Borderline Leprosy

It is further classified into three subtypes:

Borderline Tuberculoid Leprosy

In borderline tuberculoid (BT) leprosy the lesions are greater in number but smaller in size than in TT. There may be small satellite lesions around older lesions and the margins of the BT lesions are less distinct and the center is less atrophic and anesthetic. This form usually involves thickening of two or more superficial nerves.

Mid-borderline Leprosy

In mid-borderline (BB) leprosy the lesions are more numerous and heterogeneous. The lesions may become confluent or even plaques may be present. The borders are poorly defined and the erythematous rim fades into the surrounding skin. Hyperanesthesia is more common than anesthesia.

Borderline Lepromatous Leprosy

In borderline lepromatous (BL) leprosy there are a large number of asymmetrically distributed lesions which are heterogeneous in appearance. Macules, papules, plaques and nodules may all coexist. Mild anesthesia with sparing can be present.

Neuritic Leprosy

This type denotes those cases which show nerve involvement but do not have any lesions in the skin. This may be primary or secondary variety. The affected nerves become thickened and tender, producing sensory, motor and trophic changes in their area of distribution. This dysfunction leads to deformities, neuropathic ulcers and lagophthalmos which may result in serious eye complications. The common nerves involved are ulnar, lateral popliteal, tibial, greater auricular and rarely radial nerve. It can also affect fifth and seventh cranial nerves.

Lepromatous Leprosy

Most cases of lepromatous leprosy (LL) develop from borderline leprosy. This form is relatively uncommon in pediatric age group. There are two symptoms, which may precede the classical lesions by months or years, and serve to alert the physician to a possible early diagnosis: (a) nasal symptoms—stuffiness, crust formation, blood-stained discharge; and (b) edema of legs—always bilateral, prominent late in evening and which disappears after overnight rest. Skin lesions are diffusing infiltrated or numerous flat or raised, poorly defined, coppery, shiny, smooth, symmetrically distributed. Patients may have a leonine face due to loss of eyebrows and eyelashes. There is no sensory impairment in these lesions but as the disease progresses many peripheral nerves get symmetrically affected. These lesions are bacteriologically positive. The lepromin

test is negative. This form is most infectious, prone to lepra reaction and if left untreated, the prognosis is poor (Fig. 2).

Differential features of various types of leprosy are compared in Table 1.

DIAGNOSIS

Diagnosis of leprosy is based on the presence of any one of the following cardinal signs:

- Characteristic skin lesion with partial or total loss of sensation in the affected skin lesion
- Presence of acid fast bacilli in the skin smear.

Bacteriological Examination

Skin smears are useful for diagnosing multibacillary leprosy and were originally used for distinguishing between paucibacillary and multibacillary leprosy. If no definite patches or areas of thickened skin are visible, smear should be taken from ear lobules and buttocks. Smear should be made by “slit and scrape” method and stained by Ziehl-Neelsen staining. Smears are positive in LL, BL and some BB and some BT cases. It is of limited help in TT and indeterminate lesions and patients with early atypical clinical presentation. In some cases of indeterminate lesion it becomes necessary to carry out a histological examination for the purpose of diagnosis and classification of the lesion.

Bacterial Index

Bacterial index (BI) is the only objective way of monitoring the benefit of treatment. It is a semiquantitative estimation of the density of bacilli present in the skin smears and biopsies and is measured on two scales, namely the Dharmendra scale and Ridley scale. It ranges from zero to 6+ and is based on the number of bacilli (live and dead) seen in an average microscopic field of the smear using an oil immersion objective. Patients are labeled as having paucibacillary infection when there are less than or equal to 5 skin lesions. They are labeled as having multibacillary infection when there are more than or equal to 6 skin lesions. The BI can range from 0 (No bacilli in 100 oil immersion field) to 6 (more than 1000 bacilli per field).

Foot Pad Culture

Inoculation of material into the mouse foot pad is the only certain way to demonstrate the multiplication of bacilli. This method is 10 times more sensitive at detecting *M. leprae* than are slit skin smear.

Figure 2 A child with borderline lepromatous leprosy

Table 1 Differential features of various types of leprosy

Features	Types of leprosy				
	TT	BT	BB	BL	LL
Number of lesions	Single usually	Single or few	Several	Many	Very many
Size of lesions	Variable	Variable	Variable	Variable	Small
Surface of lesions	Very dry, sometimes scaly	Dry	Slightly shiny	Shiny	Shiny
Sensation in lesions	Absent	Markedly diminished	Moderately diminished	Slightly diminished	Not affected
Hair growth	Absent	Markedly diminished	Moderately diminished	Slightly diminished	Not affected
AFB in lesions	Nil	Nil or scanty	Moderate numbers	Many	Very many (plus globi)
AFB in nasal scrapings/ in nose blows	Nil	Nil	Nil	Usually nil	Very many (plus globi)
Lepromin test	Strongly positive (+++)	Weakly positive (+ or ++)	Negative	Negative	Negative

Abbreviations: AFB, acid fast bacilli; TT, tuberculoid; BT, borderline tuberculoid; BB, mid-borderline; BL, borderline lepromatous; LL, lepromatous leprosy.

Immunological Methods

These include tests for detecting cell-mediated immunity (CMI) as discussed below:

Lepromin Test

This is a test using intradermal injection of 0.1 mL of lepromin (Dharmendra or Mitsuda antigen) into the inner aspect of forearm of the individual. The reaction is read at 48 hours and 21 days to classify the stage of leprosy based on the lepromin reaction (Fernandez or Mitsuda reaction). It differentiates TT and BT, in which there is a positive delayed reaction at the injection site, from LL and BL, in which there is no reaction (a negative test result) despite the active malignant *M. leprae* infection. This test is not diagnostic, because normal uninfected people may also react. This test signifies immunity of a person, i.e., cell-mediated immunity against *M. leprae* or its antigen.

Serological Assays

These tests are expected to have value in detecting subclinical infections and in assessing efficacy of drug treatment. *Fluorescent leprosy antibody absorption test* (FLA-ABS) is used for identification of subclinical infection and is useful in identifying healthy contacts of patients. This test is 92% sensitive and 100% specific in detecting *M. leprae* specific antibody. *Radioimmunoassay* detects antibody to the cell wall antigens of *M. leprae*. Monoclonal antibodies against *M. leprae* antigens have been produced. These antibodies recognize specific and nonspecific epitopes of *M. leprae* antigens. An antibody competition test, sickle cell anemia test (SCAT) based on this approach has been found to be sensitive for detection of *M. leprae* antibody. Also, enzyme-linked immunoassays (ELISA) were found highly positive in multibacillary cases, but positivity in paucibacillary and subclinical case was quite low. Further simplified dot ELISA and dipstick ELISA using a monoclonal antibody targeting phenolic glycolipid-1 (PGL-1) have also been studied. Serological testing is not useful for diagnosis as it does not detect most paucibacillary cases and it remains positive even after treatment of multibacillary patients.

Molecular Biological Approaches

Identification of organisms can be done in a more rapid and specific way, both from culture and directly from clinical specimen, by recombinant DNA technology. Based on gene sequences of *M. leprae*, several probes have been designed in recent years.

Several gene amplification techniques, polymerase chain reaction (PCR) for amplifying *M. leprae* specific sequences from variety of specimens have been published and reported to be highly sensitive and specific.

In situ PCR, with the added advantages of providing structural correlates and permitting concomitant study of tissue pathology, improves the diagnostic yield especially in early and doubtful cases of leprosy where the histopathology is nonspecific. In situ hybridization improves the diagnostic yield significantly. In situ PCR on slit skin smear has an average positivity of 72%, better than that on skin biopsy (60%). In addition it has the added advantage of being minimally invasive and less cumbersome and can be performed even at sites from where skin biopsy is difficult. Another latest in our series in 2013 proved that *M. leprae*-specific repetitive element (RLEP) based PCR on slit skin smear is a useful tool to confirm early cases of leprosy, where skin smears are negative. It was found positive in 72% cases while skin smears only in 18% of cases.

TREATMENT

Leprosy patients should be treated with patience, perseverance and understanding. Besides the medical treatment, the patients and their parents need moral support and reassurance. Parents should be explained hygienic measures, proper diet and importance of taking treatment completely and regularly.

Multidrug Therapy

It is now a well-known fact that, simultaneous administration of several different antibacterial agents may prevent the emergence of drug resistant mutants.

The standard child (ages 10–14 years) treatment regimen for multibacillary (MB) leprosy is:

Rifampicin—450 mg once a month
Clofazimine—150 mg once a month and 50 mg every other day
Dapsone—50 mg daily
Duration—12 months

The standard child (ages 10–14 years) treatment regimen for paucibacillary (PB) leprosy is:

Rifampicin—450 mg once a month
Dapsone—50 mg daily
Duration—6 months

The dosage schedule for children below 10 years as recommended by WHO, is shown in **Table 2**.

Table 2 WHO multidrug therapy regimens

Type of leprosy	Daily, self-administered	Alternate day, self-administered	Monthly, supervised	Months of treatment
Paucibacillary	Dapsone 2 mg/kg	—	Rifampicin 10 mg/kg	6
Multibacillary	Dapsone 2 mg/kg	Clofazimine 1 mg/kg	Rifampicin 10 mg/kg, Clofazimine 6 mg/kg	12

Source: WHO, Leprosy elimination, <http://www.who.int/lep/mdt/en/>, accessed March 14, 2013

In the MDT, it is assumed that clofazimine is acceptable for children and, therefore, no child will require ethionamide/prothionamide which are potent hepatotoxic drugs. Parents should be advised to give rifampicin on empty stomach and clofazimine with meals or with a glass of milk.

Treatment of Reactions

Drugs commonly used in these conditions are antimalarials (chloroquine), antimonials, clofazimine, corticosteroids and thalidomide. Symptoms such as iritis and neuritis occurring during reactions (or occurring independently) should be properly treated in order to avoid irreversible sequelae, i.e., deformities and neuropathic ulcers.

Duration of Therapy

- Paucibacillary leprosy—PB blister packs for 6 months.
- Multibacillary leprosy—MB blister packs for 12 months.

PREVENTION

Household contacts of patients with LL, especially children, should be monitored annually for 5 years following diagnosis. Chemoprophylaxis with dapsone is no longer recommended. Various attempts have been made to develop a vaccine against leprosy, with the BCG vaccine having mixed results; other vaccines under development or being explored are the *Mycobacterium w*, *Mycobacterium* ICRC, and BCG plus heat-killed *Mycobacterium* species vaccines. A meta-analysis of 7 experimental studies and 19 observational studies found that the overall protective effect of the BCG vaccine was 26% in the experimental studies and 61% in the observational studies.

IN A NUTSHELL

1. Leprosy is a chronic disease caused by a slow multiplying bacillus, *M. leprae* with a long incubation period of 2–5 years.
2. The disease mainly affects the skin, peripheral nerves, mucosa of the upper respiratory tract and also the eyes.
3. Although not highly infectious, it is transmitted via droplets, from the nose and mouth, during close and frequent contacts with untreated cases.
4. With the help of newer diagnostic modalities, early diagnosis and treatment with MDT is possible and remains the key in eliminating the disease.
5. Leprosy is curable.
6. In WHO MDT rifampicin, clofazimine and dapsone are used for MB leprosy while rifampicin and dapsone for PB leprosy. Treatment should be continued for 6 months in PB leprosy and 12 months in MB leprosy.
7. Untreated leprosy can cause progressive and permanent damage to the skin, nerves, eyes and limbs.

Section 31 VIRAL DISEASES

Section Editors Ashok Kumar Dutta, Piyush Gupta

Chapter 31.1

Epidemiology of Viral Infections

VG Ramachandran, Piyush Gupta

To cause infection, viruses must gain entry into the body, multiply, and spread, either locally or systemically; and in the generalized infections, localize in the appropriate target organ. To be maintained in nature, infectious virions must be liberated or released in the environment, or taken up by an arthropod vector, a needle, or passed congenitally.

ROUTE OF ENTRY

Respiratory Tract

Respiratory tract is the most important entry site for the virus to enter the body. Particles 10 μm or more in diameter are usually deposited on the nasal mucosa over the turbinate bones, which project into the nasal cavity and act as baffle plates. Particles 5–10 μm in diameter may be carried to the trachea and bronchioles, where they are usually trapped in the mucus blanket. Particles of 5 μm or less are usually inhaled directly into the lungs, and some may reach the alveoli, where the virus may infect alveolar epithelial cells or be destroyed by alveolar macrophages.

All viruses that infect a host via the respiratory tract probably do so by attaching to specific receptors on epithelial cells. Following respiratory infection, the virus remains localized (e.g., rhinoviruses, parainfluenza and influenza viruses) or spread systemically (e.g., measles, chickenpox and rubella viruses).

Alimentary Tract

Many viruses are acquired by swallowing. They infect cells in the oropharynx and are then carried to the intestinal tract. The esophagus is rarely infected, probably because of its tough stratified squamous epithelium, and rapid passage of swallowed material over its surface. Virions can attach to specific receptors in the intestines or may be taken up by the specialized M-cells overlying Peyer patches in the ileum. Acid, bile and proteolytic enzymes in the gastrointestinal cells may inactivate viruses. Therefore, most of the viruses that cause intestinal infections, such as enteroviruses and rotaviruses are acid and bile resistant. Some of the enteroviruses (e.g., polio viruses), and hepatitis A and E viruses are important causes of generalized infection but do not produce signs pertaining to the intestinal tract.

Skin

Viruses entering through the skin may replicate in the skin itself to produce local lesions (e.g., papilloma viruses and pox viruses). They may enter the skin through the bite of an arthropod vector, such as a mosquito, tick or sandfly. Such viruses are called *arboviruses*. Infections can be acquired through the bite of an animal, as in rabies and iatrogenically as in the transmission of hepatitis B, C and

HIV, by contaminated needles or blood transfusion. Generalized infection of the skin, producing an exanthem such as found in measles, chickenpox, rubella and general arbovirus diseases, is due to viral dissemination through the bloodstream.

Other Routes

Herpes simplex viruses and papilloma viruses enter through the genital tract and produce lesions locally on the genitalia and perineum. HIV, human T-lymphotropic virus, and hepatitis B and C viruses may also enter through the genital tract but do not produce local lesions. Conjunctiva is a rare route of entry for some adenoviruses and a few enteroviruses.

MECHANISMS OF SPREAD

Viruses may remain localized to the body surface through which they entered—skin, respiratory tract, gastrointestinal tract, genital tract, or conjunctiva—or cause generalized infections associated with viremia and subsequent localization in particular organs.

Local Spread

On epithelial surfaces Papilloma viruses replicate in epithelial cells of skin at the site of entry, producing a localized or spreading infection in the epithelium by sequentially infecting the neighboring cells. Viruses that enter the body via the intestinal tract or respiratory tract usually have a short incubation period and usually do not invade beyond the epithelium, because the temperature of deeper tissues is higher than the optimal temperature for viral replication, though these viruses have the potential to spread (e.g., paramyxoviruses, influenza viruses and the rotaviruses).

Subepithelial invasion and lymphatic spread Virions that enter lymphatics in the subepithelium are carried to local lymph nodes and initiate an immune response. Some virions may pass straight through lymph nodes to enter the bloodstream. The extent of local inflammatory response depends on the extent of tissue damage.

Viremia

Once a virus has reached the bloodstream, usually via the lymphatic system, it can localize in any part of the body within minutes. The first entry of the virus into the blood is called *primary viremia*; this early viremia may be clinically silent. Further replication in these sites leads to the sustained liberation of much higher concentrations of virus, producing a *secondary viremia*, which in turn can lead to the establishment of infection in other parts of the body (usually liver, spleen, lymph nodes and bone marrow) and clinical symptoms.

Invasion of Skin

The skin may be invaded via the bloodstream producing erythema, and often a generalized macular, papular, vesicular or pustular rash. More severe involvement of the dermal vessels may lead to petechial or hemorrhagic rashes.

Invasion of Central Nervous System

Viruses can spread from the blood to the brain either: (1) after localizing in the blood vessels of the meninges and choroid plexus—invading the neurons from the cerebrospinal fluid; or (2) directly after localizing in blood vessels of the brain and spinal cord. Subsequent spread in the CNS can take place via the cerebrospinal fluid or by sequential infection of neural cells.

Another important route of viral infection of the CNS is via the peripheral nerves as seen in rabies, varicella and herpes simplex. Viruses may pass (1) either centripetally from the body surface to the sensory ganglia; or (2) centrifugally from the ganglia to the skin—the reactivation of herpes simplex or varicella—as zoster. The rate of travel is quite slow, at 10 mm per hour. Rabies virus infection though considered lethal, is noncytotoxic; it evokes little of the inflammatory reaction or cell necrosis, characteristic of herpes or poliovirus encephalitis. Post infectious encephalitis is most commonly seen after measles, mumps, rubella and varicella and is thought to be an autoimmune process rather than a direct result of a virus infection. Some of the viruses or virus like agents cause slow progressive diseases of the CNS and characteristic pathologic changes. These virus like agents are known as *prions* (causative agents of Creutzfeldt-Jakob disease, Kuru).

Invasion of Other Organs

Most viruses exhibit a well-defined organ and tissue tropism. The most dangerous viral infections tend to be those that cause encephalitis, pneumonia, carditis, hepatitis, or hemorrhagic fever. Infection of the sexual organs may lead to excretion of the virus in genital fluids and risk of transmission during sexual activities. Similarly, localization of virus in the salivary glands (e.g., mumps), mammary glands, kidney tubules, and lungs leads to excretion of the virus in the saliva, milk, urine, and respiratory secretions respectively. Maternal rubella and cytomegalovirus contracted in the early months of pregnancy often leads to multiple congenital abnormalities in the baby including deafness, blindness, congenital heart defects and developmental delay.

MAINTENANCE OF VIRUS IN NATURE

Shedding of the infectious virions is necessary to maintain the infection in the population; it usually occurs from one of the body openings or surfaces that are involved in both entry and exit. In generalized infections several modes of shedding are recognized: for example, hepatitis B virus, HIV, cytomegalovirus are shed in semen, cervical secretions, milk and saliva. The amount of virus shed in an excretion or secretion is important in relation to its transmission. Very low concentrations may be irrelevant unless very large volume of infected material is transferred. On the other hand, some viruses occur in such high concentrations that a minute quantity of material, for example, less than 5 μ L, can transmit infection.

Respiratory or Oropharyngeal Secretions

Viruses causing respiratory tract illnesses are shed in mucus, saliva or expelled during coughing, sneezing and talking. They are also shed from the respiratory tract in several systemic infections, such as measles, chickenpox and rubella. A few viruses, for example, the herpes viruses, cytomegalovirus and EB virus, are shed into the oral cavity from infected salivary glands, or from the lung or nasal mucosa and transmitted by salivary exchange in kissing and other social activities.

Feces

Enteric viruses are shed in the feces; the more voluminous the fluid output, the greater is the environmental contamination they cause.

Generally, they are more resistant to inactivation by environmental conditions than the enveloped respiratory viruses.

Skin

The skin is an important source of virus in diseases where transmission is by direct contact; for example, molluscum contagiosum, warts and genital herpes. Several pox viruses may be spread from animals to humans and sometimes from humans to animals by contact with skin lesions. Virus is not shed from the maculopapular skin lesions of measles, flavivirus or picornavirus infections. Herpes virus infections produce vesicular lesions in which the virus can be isolated in plenty. Even here, however, the virus shed in saliva and aerosols is much more important, as far as transmission is concerned, than that shed via the skin lesions.

Breastmilk

Several viruses, for example cytomegalovirus and HIV, are excreted in milk, which may serve as a route of transmission to the newborn infant.

Genital Secretions

Many viruses can be found in semen or vaginal secretions. They include HIV, herpes viruses, hepatitis B and C viruses.

Blood

Blood is the usual source from which arthropods acquire viruses—by inserting their proboscis into a capillary. Blood may also transfer viruses to the ovum or fetus. Hepatitis B, C and D viruses, and HIV can be spread by blood transfusion and contaminated needles.

No Shedding

Certain organs such as brain, which are not accessible to the external environment directly, are not conducive for viral shedding. For sustenance of the virus in nature, these sites of viral replication contribute little. Nevertheless, quantal increase in virus titer in such organs may be relevant for shedding to occur from a different site or for infection of blood sucking vectors.

IN A NUTSHELL

1. Viruses can enter the human body through inhalation, ingestion, infection into the skin, sexual contact and conjunctiva.
2. To be maintained in nature, the virus must be again liberated in the environment, or taken up by an arthropod vector, a needle, or transmitted transplacentally.
3. After entering the host, virus can remain localized to that area or disseminate through blood (viremia). Viremia may spread the virion to localize in particular organs.
4. Viruses can cause mild to severe illnesses, ranging from common cold to encephalitis, carditis, immune suppression, or hemorrhagic fevers.

Chapter 31.2

Poliomyelitis

Ashok Kumar Dutta

Poliomyelitis is a highly infectious, crippling, and often fatal disease, caused by any of the three serotypes of poliovirus, which mainly affects children under five years of age. It is most often recognized by acute onset flaccid paralysis of the limbs. The condition was considered in the past as one of the most feared infectious disease because of the permanent residual paralysis and disability. However, with the intelligent use of the available polio vaccines, the disease has become a rarity with only three countries of the world, e.g., Pakistan, Afghanistan and Nigeria as the only endemic countries in the world. However, there is always threat of spread of the disease from these countries and in 2013–14 several countries in African horn were affected with fresh cases of poliomyelitis from Nigeria. At present vaccine-associated paralytic poliomyelitis (VAPP) and vaccine-derived poliovirus (VDPV) are occurring in many countries. World Health Organization (WHO) aims at global eradication of both wild as well as vaccine virus causing poliomyelitis.

EPIDEMIOLOGY

Poliovirus is highly communicable disease for which human is the only reservoir. It multiplies in the intestine and is spread via fecal-oral route. The average incubation period is 7–10 days (range 4–35 days). The maximum excretion of virus occurs just before the onset of paralysis and during the first 2 weeks after the onset of paralysis. However, the virus is excreted intermittently for up to 2 months after infection. Polio cases have decreased by over 99% since 1988, from an estimated 350,000 cases to less than 100 in 2014 globally. In 2014, only three countries (Afghanistan, Nigeria and Pakistan) in the world remain polio-endemic.

ETIOPATHOGENESIS

Poliomyelitis is caused by three antigenically distinct serotypes (type 1, 2 and 3) of polioviruses. The polioviruses are nonenveloped, positive-stranded RNA viruses and belong to the genus *Enterovirus* in the family Picornaviridae. These viruses can remain active for several days at room temperature and can be stored indefinitely frozen at -20°C . It is rapidly inactivated by heat, chlorine and ultraviolet light. The most frequent causes of epidemic polio are poliovirus type 1 followed by type 3. Wild type poliovirus type 2 was eradicated from the world in 1999. Following eradication of poliovirus from most part of the globe with oral polio vaccine (OPV), there is emergence of VAPP and VDPV, which is now leading cause of acute flaccid paralysis (AFP).

Polioviruses infect cells by adsorbing to specific genetically determined receptors. The primary site of replication is small intestine and regional lymph nodes. Poliovirus which probably accesses the CNS through peripheral nerves primarily infects motor neuron cells in the spinal cord (the anterior horn cells) and the medulla oblongata. Infants born to mothers with antibodies are protected naturally against paralytic polio for a few weeks. Active immunity after natural infection (including inapparent and mild infection) is probably lifelong but protects against the infecting serotype only. Therefore polio immunization is necessary even after an attack of poliomyelitis to prevent from other serotypes.

CLINICAL MANIFESTATIONS

In 90–95% of infected individuals, poliovirus infection is inapparent. In the remaining 5–10%, one of three syndromes may occur.

Abortive polio occurs in 4–8% of infections and is characterized by a minor illness with low grade fever, sore throat, vomiting, abdominal pain, loss of appetite, and malaise. Recovery is rapid and complete; there is no paralysis.

Nonparalytic polio occurs in 1–2% of infections and is characterized by headache, neck, back and leg stiffness which occurs several days after the prodrome (fever, malaise, etc.). Presentation resembles other causes of aseptic meningitis and recovery occurs within 2–10 days.

Paralytic polio occurs in 0.5–1% of infections (i.e., one case of paralysis in every 100–200 infected children). Symptoms often occur in two phases, minor and major, and are often separated by several days without symptoms. The minor phase consists of symptoms similar to those of abortive poliomyelitis. The major phase of illness begins with muscle pain, spasms and the fever. This is followed by rapid onset of flaccid paralysis that is usually complete within 72 hours. There are three types of paralytic poliomyelitis:

1. *Spinal paralytic poliomyelitis* is the most common form of paralytic poliomyelitis, seen in approximately 80% of paralytic cases. It results from a lower motor neuron lesion of the anterior horn of the spinal cord and affects the muscles of the legs, arms and/or trunk. The affected muscles are flaccid (lower motor neuron type) and reflexes are diminished. There is no sensory involvement. Paralysis is often asymmetrical, affecting legs more often than arms. Paralytic manifestation in extremities begin proximally and progress to involve distal muscle groups (i.e., descending paralysis). Severe cases may develop quadriplegia and paralysis of the trunk, abdominal and thoracic muscles. Residual flaccid paralysis is usually present after 60 days.
2. *Bulbar polio* accounts up to 2% of paralytic cases and results from a cranial nerve lesion, resulting in respiratory insufficiency and difficulty in swallowing, nasal regurgitation and difficulty in phonation.
3. *Bulbospinal polio* accounts for approximately up to 20% of paralytic cases which is a combination of both spinal and bulbar component.

Residual paralysis As the acute phase of illness (0–4 weeks) subsides, the recovery begins in paralyzed muscles. The extent of recovery is variable depending upon the extent of damage caused to the neurons by the virus. Maximum neurological recovery of the paralyzed muscle takes place in the first 6 months of the illness but slow recovery continues up to 2 years. After 2 years, no more recovery is expected and the child is said to have “Postpolio residual paralysis”, which remains as such throughout life.

Postpolio syndrome In some individuals it has been observed that there is clinical deterioration amongst survivors after several decades. There is recent muscle weakness, poor endurance, fatigue and muscle and joint pain. Exact pathogenesis of the syndrome is not known but is attributed to be a combination of ageing process and distal muscle degeneration due to the increased metabolic demand.

Vaccine-associated paralytic poliomyelitis (VAPP) In some of the recipient of OPV in less than 1% genetic changes in VP1 gene of vaccine virus takes place and the vaccine virus becomes virulent and causes paralysis in the same recipient or among close contacts who is not immune. Approximately one case of VAPP occurs after 2.3 million of first doses and after 12 million subsequent doses.

Table 1 Differential diagnosis of paralytic (acute flaccid) poliomyelitis

Signs and symptoms	Poliomyelitis	GBS	Transverse myelitis	Traumatic neuritis
Fever at onset	High, present	Not common	Rarely present	Present
Flaccidity	Asymmetrical and proximal	Symmetrical and distal	Symmetrical lower limbs	Asymmetrical limb
DTR	Decreased or absent	Absent	Absent in LL early hyper-reflexia late	Decreased or absent
Sensation	Myalgia, no sensory loss	Cramps, tingling hypoesthesia of palms and soles	Loss of sensation with sensory level	Pain in gluteal region
Cranial nerves involvement	Only in bulbar and bulbospinal	Often present VII, IV, X, XI, XII	Absent	Absent
CSF, WBCs	Increased	< 10 WBCs	Normal	Normal
CSF, protein	Slight increase	High	Normal or slight increase	Normal
Bladder dysfunction	Absent	Transient	Present	Never
Nerve conduction velocity—third week	Abnormal Anterior horn cell disease	Abnormal demyelination	No diagnostic value	Abnormal in sciatic nerve
EMG-third week	Abnormal	Normal	Normal	Normal

Abbreviations: GBS, Guillain-Barré syndrome; DTR, deep tendon reflexes; LL, lower limb; CSF, cerebrospinal fluid; WBC, white blood cells; EMG, electromyography.

According to WHO, approximately 500 cases are reported every year. VAPP is clinically indistinguishable from paralysis due to wild poliovirus.

Vaccine-derived poliovirus (VDPV) It is derivative of Sabin strain from OPV which exhibits about 1–15% genetic changes in the VP1 gene and usually transmits disease to nonimmune individual. The strain has potential for human infection and paralysis including sustained circulation and spreading disease in other countries through human travel and is a serious threat to spread of the disease in various countries of the world. In the last 5 years more than 500 cases of circulating vaccine-derived poliovirus (cVDPV) type 2 diseases have occurred in various countries which were declared polio free. This mutant strain is of three types:

Circulating vaccine-derived poliovirus (cVDPV) This emerges in areas with poor OPV coverage and chances of sustained person to person spread. WHO considers cVDPV as serious threat to polio eradication process.

Immunodeficient-associated VDPV (iVDPV) This strain is isolated from persons with primary immune deficiency states who exhibit prolonged infection after OPV exposure. These strains can persist for over 20 years.

Ambiguous vaccine-derived poliovirus (aVDPV) This strain is clinical isolate from nonimmunocompromised individual or environmental isolation from unidentified source.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of abortive and nonparalytic polio includes other viral fevers. Paralytic poliomyelitis needs differentiation from other causes of AFP. Paralytic poliomyelitis, Guillain-Barre syndrome, traumatic neuritis and transverse myelitis represent the most common causes of AFP, but the complete differential diagnosis includes numerous etiologies (hypokalemia, encephalitis, meningitis and other enterovirus infections, polymyositis, peripheral neuritis, myasthenia and other myopathies, etc.). Distinguishing characteristic of paralytic polio are asymmetric, AFP, mostly involving proximal muscles with fever and muscular pain at onset, rapid progression from onset to maximum paralysis (usually < 4 days), intact sensory nerve function, and most

often, residual paralysis or weakness after 60 days. Salient features of differentiation are summarized in **Table 1**.

DIAGNOSIS

Clinical Diagnosis

Characteristic clinical presentation of acute lower motor neuron type of asymmetrical paralysis of proximal limb muscles without any sensory involvement is highly suggestive of poliomyelitis. However, all cases of AFP cases should be investigated by sending a stool sample for isolation of virus.

Stool for Virus Isolation

Virus can be found in the feces from the onset to up to 8 or more weeks after paralysis, with the highest probability of detection during the first 2 weeks after onset. Isolation of wild poliovirus from stool is the recommended method for laboratory confirmation of paralytic poliomyelitis. Two stool specimens are collected from each case for laboratory confirmation. Adequate stool specimen is defined as two specimens collected at least 24 hours apart within 14 days of onset of paralysis. Each sample should have volume (8–10 g or thumb size) and sent to a WHO accredited laboratory in good condition with no desiccation, leakage and maintaining cold chain.

TREATMENT

The aim of treatment is to promote recovery, and to minimize residual muscle paralysis and disability. Treatment of the child with paralytic poliomyelitis varies with stage of illness and the severity of paralysis. Children with bulbospinal polio and respiratory paralysis would require hospitalization. In acute stage children with isolated limb/limbs paralysis should be advised complete rest, proper positioning of the affected limb and passive range of movement at the joints. Massage and intramuscular injection should be avoided during acute phase of illness. The child should be made to lie on firm bed and maintain limbs in neutral position. The child should lie with trunk and hip straight with slight flexion (5–10°) at knees and feet at right angle at ankle joint. This position can be maintained with pillows, rolled towels

or sand bags. The support should also be given on lateral sides of limb/limbs to prevent external rotation. Warm moist fomentations and passive range of movements of all the joints of affected limb/limbs should be given. As the acute phase of illness subsides, recovery in muscle power is helped by giving physiotherapy in the form of active exercises aimed at strengthening weak muscle groups, improvement of functional skills of the child, helping ambulation and prevention of deformities. Physiotherapy plays an important role in management of children during recovery and postpolio residual paralysis stage. Some children with fixed deformities and contractures may require orthopedic surgery.

PREVENTION OF POLIOMYELITIS

Two effective polio vaccines, the inactivated poliovirus vaccine (IPV), which was the first vaccine to become available in 1955, and the live attenuated OPV, licensed in 1959 are available for preventing the disease.

Oral polio vaccine induces both circulating antibody and intestinal immunity, and by secondary spread, probably protects susceptible contacts. The seroconversion after three doses of OPV has been reported to be more than 95% in developed countries but data from developing countries has shown wide variation in seroconversion and protective efficacy with rates varying from 70% against type 1 and 3 and approximately 90% for type 2 strain. OPV is most often formulated as a trivalent vaccine, containing antigens for all three poliovirus serotypes (1, 2 and 3). Trivalent vaccine is used for routine immunization of infants as well as most of the pulse polio immunization rounds. OPV is also available as a monovalent vaccine (mOPV) and bivalent (P1, P3), and has been used in specific areas where surveillance showed ongoing P1 and P3 wild virus transmission. OPV should be administered directly into the mouth. Each single dose consists of two drops. OPV is given at birth followed by three more doses at 6, 10 and 14 weeks and at 16–18 months. In addition, OPV doses are recommended as per pulse polio recommendations from time to time. OPV is one of the most heat-sensitive vaccines in common use. The vaccine should be stored at 2–8°C at all times. Unopened vials of OPV may be stored for up to 6 months at –20°C. The potency is monitored with color changes in vaccine vial monitor.

Inactivated polio vaccine Also known as Salk vaccine, IPV is a mixture of the three polioviruses made by harvesting cell culture supernatants and submitting them to inactivation by formalin. When used as primary vaccination of infants, the vaccine produces seroconversion in 90–95% of children. IPV is relatively heat stable. Risk of vaccine-associated paralysis is nonexistent with IPV and can be safely used in immunocompromised individuals.

Strategy for Polio Eradication

In May 1988, the World Health Assembly committed the member nations of the WHO to achieving the goal of global eradication of

poliomyelitis. Since most of the countries in the world are now declared as polio free, the end game strategy has been defined now by the WHO strategic advisory board on polio eradication as complete eradication and containment of all wild, vaccine and Sabin poliovirus from the world.

End Game

Trivalent OPV shall be discontinued by 2015/2016 and there will be switch to bivalent OPV. Six months before this switch, every child should receive at least one dose of inactivated polio vaccine dose with third dose of DPT at 14 weeks of age in all countries of the world who are using OPV. This strategy shall prevent circulating VDPV by augmenting the immunity induced by earlier doses of trivalent OPV. By 2019 there shall be complete cessation of OPV and at least one dose of IPV will be given to each child till 2024.

IN A NUTSHELL

1. Poliomyelitis is an important public health problem which cripples the individual. The wild virus disease is now endemic in only three countries of the world.
2. Vaccine-associated paralytic poliomyelitis (VAPP) and VDPV are the two major threats in the ultimate eradication of poliomyelitis.
3. Paralytic poliomyelitis presents as AFP (acute flaccid paralysis) which is asymmetrical in nature.
4. The important differential diagnosis of poliomyelitis includes Guillain-Barre syndrome, transverse myelitis and traumatic neuritis.
5. There are two excellent vaccines available for prevention of poliomyelitis and intelligent use of both these vaccines has led to almost eradication of this once considered dreaded disease.

Chapter 31.3

Measles

Shilpa Khanna Arora, Piyush Gupta

Measles (*Morbilli*, English Measles or *Rubeola*) is a highly contagious viral infection of the childhood. Though measles vaccination resulted in a 78% drop in measles deaths between 2000 and 2012 worldwide, the disease is still a significant cause of morbidity and mortality amongst children of developing countries. It is the leading cause of death among vaccine-preventable diseases, mainly attacking the undernourished children. Uncomplicated illness lasts for 7–10 days conferring lifelong immunity.

EPIDEMIOLOGY

Measles mainly affect children under 2 years of age, especially in developing nations with more than 80% of cases occurring in under-fives. Both sexes are equally affected; however, complication rates are higher in males. WHO estimated 122,000 measles deaths globally in 2012, i.e., amounting to almost 14 deaths every hour. These deaths represent 50–60% of deaths due to all vaccine preventable diseases. The disease burden is high in India due to poor coverage under routine immunization (48.4%, NFHS-3), and nonavailability of a second opportunity for measles vaccination in many of the states. It is estimated that more than 100,000 children die due to measles in India every year. The majority of the deaths occur in areas with poor vaccine coverage.

AGENT

Measles virus is a single stranded RNA virus belonging to genus *Morbillivirus* under family Paramyxoviridae. The virus is composed of an outer envelope and internal helical nucleocapsid. Envelope contains proteins F, H and M, and has spikes on its surface. Hemagglutinin (H) and fusion (F) proteins are important as antibodies against these two help in body's defense. The virus is rapidly inactivated by heat and ultraviolet rays. Man is the only natural host and source of measles virus. Carrier state does not exist.

TRANSMISSION

Measles spreads from the infected person to a normal individual by the respiratory route or conjunctivae via large droplets or small droplet aerosols. Sometimes large droplets or direct person-to-person contact may also spread the disease. The virus can stay suspended in atmosphere for 1 hour, hence face to face contact with the case is not necessary for the disease to occur. Period of infectivity is usually 4 days before and 5 days after the onset of rash. Immunocompromised hosts tend to remain infective throughout the illness. As measles virus is highly contagious, a 5% susceptible population is sufficient to sustain periodic outbreaks in otherwise highly vaccinated populations. More than 90% of the exposed susceptible contacts manifest the disease indicating a high infectivity.

IMMUNITY

Measles natural infection confers lifelong immunity. Serum antibodies to viral hemagglutinin, hemolysin, and complement are observed following an infection. Hemagglutinin inhibiting and neutralizing antibodies appear after 2 weeks, peak at 4–6 weeks, and decrease over a year, but persist lifelong. Children with defective cell-mediated responses are more prone to die from progressive measles infection. Acute measles results in a temporary

defect in neutrophil motility. T, B, and null lymphocytes are reduced. Interferon response appears after 10 days and coincides with recovery from acute infection. Transplacentally-acquired antibodies protect the infant for first 6–8 months of life and tend to hamper the response to live-attenuated measles vaccine given before the age of 9 months.

PATHOGENESIS

Aerosols carrying the virus enter and infect the respiratory tract where virus multiplies in tracheal and bronchial epithelial cells. This results in primary viremia (day 2–3) that infects local lymphatic tissues, perhaps carried by pulmonary macrophages. Following the amplification of measles virus in regional lymph nodes, a predominantly cell-associated viremia disseminates the virus to various organs by secondary viremia (day 5–7) resulting in systemic symptoms prior to the appearance of rash. Two types of giant cells are seen in measles: Warthin-Finkeldey cells of reticuloendothelial system and epithelial giant cells of respiratory and other epithelia. In individuals with deficiencies in cellular immunity, the virus causes progressive and often fatal-giant cell pneumonia. In immune-competent subjects, although the measles virus is cleared by virus-specific immune response, the general immune response to other antigens is suppressed. This immune-suppression is marked by decrease in delayed-type hypersensitivity, interleukin-12 production, and antigen-specific lymphoproliferative responses that persist for weeks to months after the acute infection. Immunosuppression may predispose individuals to severe bacterial infection, particularly bronchopneumonia, a major cause of measles-related mortality among younger children.

CLINICAL FEATURES

The *incubation period* from exposure to onset of symptoms ranges from 8 days to 12 days. The *prodromal phase* is characterized by fever, cough, coryza, rhinitis, conjunctivitis, malaise, and anorexia. Fever is moderate grade, continuous, and persists for at least 1 week. The *enanthematous phase* is characterized by Koplik spots on the buccal mucosa which appear on second or third day of fever. These appear as bluish-gray specks or *grains of sand* on a red base at the level of premolars. They may also occur on lips, palate, conjunctivae, gums, and vagina. In 1–2 days Koplik spots start fading or sloughing and the exanthematous rash begins to appear around fourth day of illness marking the onset of *exanthematous phase*. The rash starts from the face and neck, near the hairline; it then proceeds to the trunk, extremities, palms, and soles and lasts for about 5 days. Patients appear most ill during the first or second day of the rash and then the symptoms begin to subside. The rash is erythematous and maculopapular (**Fig. 1**). It blanches on pressure during the initial 2–3 days. Later it begins to coalesce especially on face and trunk. In later stage, the rash does not blanch and starts darkening. Generalized lymphadenopathy, mild hepatomegaly, and appendicitis may occur because of generalized involvement of lymphoid tissue. After 5 days, the *recovery phase* starts and the rash starts disappearing in the sequence in which it had appeared, leaving behind desquamated areas that spare the palms and soles (**Fig. 2**).

The typical rash may be absent in patients with underlying deficiencies in cellular immunity. Children with partial immunity develop a *modified measles* that is a milder illness with less severe symptoms and shorter duration of fever and rash. These patients do not shed virus and hence do not transmit infection to their contacts. *Hemorrhagic measles* is a severe form characterized by generalized bleeding, altered sensorium, convulsions, coma, and a high fatality rate.

COMPLICATIONS

As discussed, measles virus weakens the immune system resulting in complications that may involve virtually any of the organ system. Complications occur in almost 30% cases of measles and are responsible for the large amount of morbidity and mortality caused this infection. Malnutrition, younger age, lack of breastfeeding, underlying malignancy or immunodeficiency, and low serum retinol (vitamin A) levels predispose to a more severe and complicated disease course.

Respiratory system complications include otitis media, sinusitis, mastoiditis, retropharyngeal abscess, tracheitis, laryngo-tracheobronchitis (croup) and bronchopneumonia. Primary tuberculosis is known to flare up following measles. Pneumonia is the most common complication in Indian context, whereas otitis media is most common in western countries. Pneumonia may be caused either by the measles virus itself or because of superimposed bacterial infection by *Staphylococcus aureus*,

Streptococcus pneumoniae, *Haemophilus influenzae*, or gram-negative bacilli including *Klebsiella*, *E. coli*, and *Pseudomonas*.

The common digestive system complications include vomiting, diarrhea, and dysentery. Giant cell formation in the gastrointestinal epithelium causes diarrhea that often gets prolonged as persistent diarrhea in poorly nourished children, hence precipitating severe acute malnutrition. Appendicitis is known to occur secondary to luminal lymphoid hyperplasia. Rare complications include hepatitis and ileocolitis.

Clinically inapparent cerebral dysfunction is observed in almost 50% of cases with uncomplicated measles in the form of electroencephalographic abnormalities and cerebrospinal fluid (CSF) pleocytosis. The most common clinically apparent central nervous system (CNS) complication is acute postinfectious measles encephalitis (APME) that occurs in approximately 0.1% of cases and leads to mortality in approximately 20% of the affected subjects. It is considered to result indirectly from the virus-induced pathogenic immune response as measles virus is generally not detected in the CNS. The onset occurs in the first week of illness. Approximately one-third develop long-term sequel. Two rare but inevitably fatal CNS complications of measles are subacute sclerosing panencephalitis (SSPE) and measles inclusion body encephalitis (MIBE). Both of these complications arise after clinically silent duration of months to years after acute infection. In contrast to APME, measles virus is abundantly detected in the CNS of subjects SSPE and MIBE. Whereas SSPE develops in fully immunocompetent individuals, MIBE is generally observed in immunocompromised patients.

Subacute sclerosing panencephalitis is a rare degenerative disease of CNS that results due to persistence of measles virus infection acquired earlier in life. It occurs with a rate of 4–11 cases of SSPE per 100,000 cases of measles. The incidence is higher in children who acquired the disease at an early age. Generally the disease process manifests 7–10 years after measles infection, but cases have been reported to occur as early as 1 month to up to 27 years after the primary infection. Pathogenesis of SSPE involves an altered measles virus lacking one of the structural proteins enabling the virus to perpetuate within the CNS cells. Higher incidence of the disease amongst subjects who acquired the disease at an earlier age suggests role of an aberrant or immature immune system as well in disease causation. The disease is characterized by gradually progressive behavioral changes like irritability, reduced attention span and temper tantrums. Poor school performance due to intellectual deterioration is a common symptom. These subtle symptoms may not provide a clue toward diagnosis but the next stage characterized by involuntary movements and myoclonic jerks in presence of maintained sensorium should prompt the clinician to consider SSPE. In late stages extrapyramidal symptoms like choreoathetosis, immobility, dystonia and rigidity appear as a result of progressive degeneration of the basal ganglia. Following this the sensorium starts deteriorating leading to dementia, stupor, coma, and finally death ensues as the vital centers located in the brainstem get involved. The stages of progression of the disease may vary among subjects. At times cognitive decline may continue for many years before manifesting the severe neuromuscular symptoms leading to delay in diagnosis. SSPE is diagnosed on the basis of the typical clinical features and at least one of the following laboratory findings, *viz.* presence of periodic complexes in electroencephalogram, elevated anti-measles IgG in CSF and serum, or isolation of virus or viral antigens from brain tissue. Postmortem diagnosis may also be established by demonstration of typical histological features in brain biopsy specimen. The sequence analysis of viral isolates from SSPE patients has shown that the disease is caused only by wild virus and never by vaccine virus. SSPE should always be suspected as a differential diagnosis

in presence of the above mentioned clinical features even if there is no definite past history of measles infection as the patient might have had an ill-defined or mild infection either due to passively acquired maternal antibodies or due to immunization. There is no definitive cure for SSPE although many drugs like amantadine, inosiplex (isoprinosine), and intraventricular interferon- μ (IFN- μ) have been tried with conflicting results. The average survival is 1–2 years since the onset of symptoms. Spontaneous remission has been reported in very few cases. The incidence of SSPE has decreased in nations with good measles vaccination coverage.

Other less commonly reported complications of measles include myocarditis, Stevens Johnson syndrome, bacteremia, cellulites, acute glomerulonephritis, and consumption coagulopathy.

Mortality from measles is often the result of complications that follow the derangement in immune system and respiratory mucosa. The leading cause of death from measles is pneumonia. Case-fatality rate is highest in under-five children.

APPROACH TO DIAGNOSIS

The clinical case definition of measles includes generalized maculopapular rash lasting more than or equal to 3 days; temperature of more than or equal to 38.3°C (101°F); and presence of cough, coryza, or conjunctivitis. Koplik spots, if present, are pathognomonic of measles. However, they are present in 50–70% children only. Inapparent or modified measles might pose a diagnostic challenge. Laboratory confirmation of the disease is not required in regions where the disease is common. In countries with good measles vaccine coverage and low prevalence of the disease, diagnosis may be confirmed by serology; viral isolation from blood, urine or respiratory secretions, or by PCR. Serum IgM becomes positive after 2–3 days after the onset of rash and persists for next 4–5 weeks. In case the sample is collected within first 3 days of onset of rash, demonstration of a fourfold rise in IgG in convalescent sera, i.e., after 2–3 weeks will confirm the diagnosis. Viral culture and molecular diagnosis by PCR are generally utilized for research purpose.

The total lymphocyte count is reduced with a greater reduction in lymphocytes as compared to neutrophils during the illness. Acute phase reactants like erythrocyte sedimentation rate and C-reactive protein are generally not altered. A rise in these would point toward presence of a superadded bacterial infection.

DIFFERENTIAL DIAGNOSIS

The differential diagnoses of fever with maculopapular rash include rubella, infectious mononucleosis, roseola, fifth disease, group A streptococcal infection, meningococemia, dengue fever, rickettsial infections, mycoplasma infections, Kawasaki disease, and drug eruptions.

Rubella is a milder disease with a characteristic postoccipital lymphadenopathy. Infectious mononucleosis should be suspected if there is generalized lymphadenopathy and hepatosplenomegaly. Children with dengue fever have a rash that is confluent and also involves palms and soles. Meningococcal and streptococcal rash are characterized by petechiae, purpura, associated with a generalized toxic look. Rash of roseola infantum (caused by herpesvirus-6) typically starts from trunk and is associated with periorbital edema. Fifth disease caused by human parvovirus B 19 (HPV 19) is characterized by an erythematous rash on the cheeks, giving these children a typical *slapped cheek* appearance.

MANAGEMENT

Uncomplicated measles, like any other acute viral illness, generally resolves on its own within 7–10 days. Hence the treatment is mainly symptomatic and directed toward managing fever, cough,

hydration and nutrition. These children can be easily managed at home and proper hygiene must be maintained. Measles being a highly contagious infection, the patients should be advised to practice respiratory hygiene measures and should be preferably isolated from unimmunized contacts.

WHO and UNICEF recommend administration of two doses of vitamin A supplements given 24 hours apart, to all children diagnosed with measles, in communities where measles-related mortality is more than 1%. There is evidence that administration of vitamin A not only reduces ophthalmic complications but it also decreases the severity of other complications as well as mortality due to measles by 50%.

Secondary bacterial infections are managed with appropriate antibiotics. Patients with complicated measles require hospitalization and should be managed accordingly.

PREVENTION

Measles vaccine is a live attenuated vaccine available in India as a monovalent vaccine as well as in combination with mumps and rubella as measles, mumps and rubella (MMR) vaccine with both the preparations having equal efficacy. The vaccine is available in lyophilized form. The reconstituted vaccine is administered subcutaneously in the upper arm or anterolateral aspect of thigh in a dose of 0.5 mL. It may be given intramuscularly as well. Its shelf-life is at least 1 year at 4–8°C. The most popular strains of measles vaccine-viruses, namely *Schwarz*, *Moraten* and *Edmonston-Zagreb* (EZ) were derived by further attenuation from the *Edmonston B* strain, which itself was attenuated from the *Edmonston A* strain. In India, Serum Institute, Pune uses EZ strain cultured in human diploid cells to manufacture the vaccine. The minimum recommended potency is 1,000 median cell culture infectious doses (CCID₅₀) of virus. Diluents must not be frozen. One hour after reconstitution, its potency drops by 50% at 20°C and if kept at 37°C almost all potency is lost. Moreover, several cases of staphylococcal toxic shock syndrome with high mortality have occurred in India after giving reconstituted measles vaccine stored for 1 or more days. Hence it must be stored at 4–8°C after reconstitution and discarded after 4 hours.

Transplacentally-acquired maternal antibodies protect not only the infants against the disease but also neutralize the immunogenic property of the vaccine if administered during infancy. Hence it should be administered at an age when majority of infants would have lost these antibodies and are susceptible to develop the disease. Therefore, in developing countries the recommended minimum age is 9 months when almost 85–95% of those vaccinated get seroconverted.

Depending upon the strain of vaccine virus, 10–20% of vaccines may develop mild to moderate fever about 6–8 days after receiving measles vaccine. It lasts for 1–3 days, and is not associated with malaise, etc. One to five percent of children may develop a few red spots on the trunk during this period.

The vaccine is contraindicated in pregnancy, significantly immunocompromised states such as leukemia, administration of antimetabolites, radiations or corticosteroids, and recent administration of immune-globulin within last 3 months. Asymptomatic HIV infection is *not* a contraindication for measles vaccination because of risk of severe life threatening measles in children with HIV infection. Hypersensitivity to eggs and neomycin is a contraindication for vaccine prepared from chick embryo cells but not for the one prepared from human diploid cell cultures.

In case of an outbreak, post-exposure immunization with live measles vaccine within 72 hours of exposure to a case may modify the illness and provide protection in certain cases. Thus, in school-based outbreaks, this may be used as a strategy for control.

Passive immunization with measles immunoglobulin within 6 days of exposure in a susceptible contact may also prevent or modify the disease. The dose is 0.25–0.5 mL/kg body weight up to a maximum of 15 mL and is given intramuscularly. It is indicated for children less than 1 year, pregnant and immunocompromised subjects who are more likely to develop complications of the disease. The vaccine must be administered at least 3 months after passive immunization. It is not recommended for controlling measles outbreak.

The EZ strain is being developed as an aerosol vaccine to immunize infants as young as 4–6 months, against measles. By utilizing the respiratory route, it is hoped to avoid neutralization by any maternal IgG antibodies that may be present.

MEASLES CONTROL STRATEGY

Routine measles vaccination coverage has been selected as an indicator of progress toward achieving MDG 4 due to the facts that measles vaccination has the potential to reduce child mortality as well as that measles vaccination coverage can be considered a marker of access to child health services. Surveys have demonstrated that the overall coverage for measles vaccine given between 9 months and 12 months is around 70%. Considering the vaccine efficacy to be around 85% for vaccination at 9 months, only around 60% ($70\% \times 85\% = 60\%$) of annual birth cohorts is actually protected against the disease leaving the rest 40% to be susceptible to measles. The second opportunity for immunization represents another opportunity for immunization for children who missed the first dose in the routine program and for children who failed to develop immunity after their first dose. Thus it is recommended by WHO and UNICEF to administer two doses of measles containing vaccine to ensure adequate protection against the disease. Routine measles vaccination for children combined with mass immunization campaigns in countries with high case and death rates are key public health strategies to reduce global measles deaths.

National Technical Advisory Group of the Government of India has recommended strengthening the coverage of routine measles immunization at 9–12 months of age; reducing the drop outs; vaccination of children at the earliest up to 5 years, who have missed the 9–12 months schedule and reporting children vaccinated over 1 year. The Group has also laid stress on skillful and standardized management of measles outbreaks.

Measles can be eradicated because man is the only reservoir of the virus; the disease occurs due to only one serotype and an effective vaccine is available.

IN A NUTSHELL

1. Measles is a highly contagious acute viral illness that generally lasts for 7–10 days and confers lifelong immunity.
2. Measles is the leading cause of death amongst all the vaccine-preventable diseases. The disease burden is high in India due to poor coverage under routine immunization and nonavailability of a second opportunity for measles vaccination in many of the states.
3. The virus spreads by the respiratory route or conjunctivae. Period of infectivity is usually 4 days before and 5 days after the onset of rash.
4. The incubation period ranges from 8 days to 12 days. The illness starts with the prodromal phase followed by enanthematous, exanthematous and recovery phases.
5. Malnutrition, younger age, lack of breastfeeding, underlying malignancy or immunodeficiency, and low serum retinol (vitamin A) levels predispose to a more severe and complicated disease course.
6. The clinical case definition of measles includes generalized maculopapular rash lasting more than or equal to 3 days; temperature of more than or equal to 38.3°C (101°F) and presence of cough, coryza, or conjunctivitis. Koplik spots, if present, are pathognomonic of measles.
7. The differential diagnoses of fever with maculopapular rash include rubella, infectious mononucleosis, roseola, fifth disease, group A streptococcal infection, meningococemia, dengue fever, rickettsial infections, mycoplasma infections, Kawasaki disease and drug eruptions.
8. Uncomplicated measles, like any other acute viral illness, generally resolves on its own within 7–10 days. Hence the treatment is mainly symptomatic and directed toward managing fever, cough, hydration and nutrition. Administration of two doses of vitamin A supplements given 24 hours apart, to all children diagnosed with measles has been shown to reduce mortality.
9. Complications of measles can affect respiratory, gastrointestinal and CNS. SSPE is an inevitably fatal late CNS complication of measles.
10. Effective and safe live attenuated measles vaccine is available in India as monovalent vaccine as well as part of MMR vaccine. WHO and UNICEF recommend administration of two doses of measles containing vaccine to ensure adequate protection against the disease.

Chapter 31.4

Mumps

Shilpa Khanna Arora, Piyush Gupta

Mumps is a self-limiting, acute viral illness involving parotid and other salivary glands. It is characterized by fever, and bilateral tender swelling of salivary glands. Natural infection with mumps virus confers lifelong protection. The disease is vaccine preventable and the incidence has markedly declined in populations receiving mumps vaccine as part of routine immunization.

EPIDEMIOLOGY

The estimated incidence of mumps is around 300 per 100,000 population with majority of cases being unreported due to relatively uneventful nature of the illness. The incidence peaks during winter and spring season. Cyclic epidemic peaks are observed every 2–5 years in poorly immunized populations.

The disease occurs predominantly in children between 5 years and 15 years. Countries like USA after having introduced one dose of mumps containing vaccine in the national schedule, observed an epidemiological shift in the age group of the affected patients with more epidemics occurring in adolescents and young adults. This was attributed to waning of the vaccine-induced immune response which is considered weaker than the naturally acquired one. Inclusion of two doses of mumps containing vaccine in their national schedule has led to drastic decline in the number of cases of mumps. Mumps produces more severe disease in adults. The disease is not generally seen in infants due to the presence of transplacentally-acquired antibodies. There is no sex predilection for parotitis but CNS complications are more frequent in males. Mumps infection during first trimester increases the risk of abortion. Though the virus is known to cross placenta, it is not known to cause any congenital malformations in the fetus.

AGENT

The disease is caused by mumps virus (genus *Rubulavirus*; family Paramyxoviridae). It is a single stranded RNA virus having a lipoprotein capsule that contains some structural proteins including hemagglutinin, neuraminidase and fusion proteins that aid in viral entry within the host cells. The virus can be obtained from the saliva swab of the infected patients 7 days before and 8 days after the onset of salivary gland swelling that corresponds to the period of infectivity. The period in which a person is maximally infective is generally 2 days before till 5 days after the onset of parotid gland swelling. There is only one serotype of the virus. Humans are the only known hosts for the virus. Subclinical cases are very common and these may transmit the infection to susceptible persons. Carrier state does not exist.

PATHOGENESIS

Virus is transmitted through saliva or by respiratory droplets. The virus may also be found in urine and cerebrospinal fluid. The virus enters human body through the inhalational route and seeds the epithelium of upper respiratory tract, where it replicates. Absorption of virus in host cell is facilitated by hemagglutinin-neuraminidase (HN) surface glycoprotein, while F (fusion) glycoprotein mediates viral penetration into the cell. This is followed by regional lymphoid invasion and viremia. Mumps virus selectively targets the salivary glands, central nervous system, pancreas, testes, heart, liver, kidneys, thyroid, and joints. The virus evokes a lymphocytic response in infected tissue, with ultimate

necrosis of the salivary epithelium. Mumps virus enters the central nervous system via the choroid plexus. Cerebrospinal fluid is also characterized by a lymphocytic response. Focal ischemic infarcts are observed in the testis.

CLINICAL FEATURES

The disease can vary from a mild upper respiratory illness to viremia with widespread systemic involvement. Incubation period is generally 16–18 days but it may vary from 12 days to 25 days. The prodromal phase lasts for 1–2 days during which the child has mild to moderate grade fever, malaise, headache, vomiting, nausea and impaired appetite. The most common clinical presentation of the illness is parotitis that occurs in 30–40% of affected children. Other reported sites of infection are the testes, pancreas, eyes, ovaries, central nervous system, joints, and kidneys. The infection may remain asymptomatic in 20–30% of cases.

Parotitis is the hallmark presenting feature of mumps that is characterized by enlargement of one of the parotid glands to begin with and becomes bilateral in majority of the cases within 72 hours. Swelling of parotid is preceded by pain near the ear lobe and also difficulty in swallowing and chewing. Swelling results in obliteration of the angle of the jaw and lifting of the ipsilateral ear lobe, upward and outward. The swelling increases in size for 3–4 days. Disease may remain unilateral in 30% cases. In 10% of cases there occurs inflammation and swelling of other salivary glands as well. Lymphatic obstruction in facial and neck planes may result in local edema, extending up to sternum.

Recovery begins as fever begins to subside in 3–5 days. Parotid swelling starts receding after 5 days. It may take 10–14 days for the swelling to subside completely.

COMPLICATIONS

Neurological manifestations are the most common extrasalivary manifestation of mumps infection. The frequency with which mumps virus infects the nervous system is quite high to the extent that it is regarded as a neurotropic virus by many researchers. The CNS affliction of mumps virus may range from relatively benign aseptic meningitis in majority of the cases to severe meningoencephalitis in a small number of cases. The neurological complications are seen more often in males as compared to females (ratio 3:1 to 4:1). Asymptomatic pleocytosis in CSF is seen to occur in almost 50% of all children with mumps but the incidence of symptomatic disease is around 10–15% of the cases.

Aseptic meningitis is the most common complication with an incidence of around 10% of all the cases of mumps. It is manifested as severe headache, photophobia, and neck stiffness due to spasm of the spinal muscles. It appears within a few days of parotid swelling and generally resolves in 7 days without any complication. Mumps meningitis may also occur in absence of any parotid swelling. Death due to mumps is exceedingly rare, and is mostly caused by mumps encephalitis. Encephalitis occurs in 0.1% of the cases which is much less than meningitis and is characterized by seizures, altered sensorium or focal neurological deficits. It may manifest before, with, or after the appearance of parotid swelling. *Early onset encephalitis* occurs within 1–2 weeks of onset of swelling and is due to mumps infection of the brain. *Late onset encephalitis* is an immune-mediated demyelinating condition. Some cases experience ataxia, behavioral changes, and abnormalities in electroencephalography during convalescence, but they also resolve after a few weeks. Mortality occurs in about 1.5% of the cases. Long-term morbidities like permanent unilateral sensorineural hearing loss are not very common (0.005%).

Other neurological manifestations of mumps include cerebellar ataxia, acute disseminated encephalomyelitis, aqueductal stenosis,

facial nerve involvement, auditory nerve involvement leading to permanent hearing deficit, transverse myelitis, and Guillain-Barré syndrome. Although most patients recover without prolonged sequel, the mortality rate is reported to be up to 1.4%.

Epididymo-orchitis occurs in about 30% of postpubertal adolescents with mumps but is rare in prepubertal males. It is bilateral in less than one-third of the cases. Although testicular atrophy is known to occur, sterility is rare. In postpubertal adolescent girls, mastitis and oophoritis can occur. Pancreatitis is seen in about 4% of patients with mumps and may occur even in absence of parotitis. There is evidence suggesting that mumps virus infection of the pancreatic beta cells may trigger the onset of insulin-dependent diabetes mellitus. Additional rare complications include glomerulonephritis, arthritis, myocarditis, endocardial fibroelastosis, thrombocytopenic purpura, mastitis, thyroiditis and keratouveitis.

APPROACH TO DIAGNOSIS

In populations having a high prevalence of mumps, it is diagnosed on the basis of the typical clinical presentation as described above. History of exposure to a case of mumps 2–3 weeks back would support the diagnosis. Laboratory confirmation of parotitis can be made on the basis of elevated serum amylase levels. Presence of leukopenia with relative lymphocytosis indicates a viral etiology. CNS infections exhibit a lymphocytic pleocytosis in cerebrospinal fluid, with hypoglycorrhachia.

The diagnosis of mumps in populations with low disease prevalence can be difficult and require viral isolation or detection of mumps virus nucleic acid by reverse transcriptase-polymerase chain reaction. This may be carried out in specimens from exudates of Stensen's duct using buccal swabs, nasopharyngeal swabs, throat washings, saliva, urine, blood, or cerebrospinal fluid. Though the mumps virus can be isolated from 7 days before up until 9 days after the onset of parotitis, the yield is highest only during the first few days of the illness in highly immunized populations. Thus clinical specimens must be obtained within 1–3 days after the onset of parotitis. Serological diagnosis can be made by detection of mumps-specific IgM antibody, or by a significant increase between acute and convalescent titers in serum mumps IgG antibody by complement fixation, hemagglutination inhibition, or enzyme immunoassay. Serological confirmation in highly immunized populations may be challenging as the IgM response may be absent or short lived; and acute IgG titers already might be high, so no significant increase can be detected between acute and convalescent specimens. Hence, a negative IgM in an immunized child does not exclude the diagnosis.

DIFFERENTIAL DIAGNOSIS

Parotitis characteristically results in obliteration of the angle of the jaw and lifting of the ipsilateral ear lobe in an upward and outward direction. At times one may need to differentiate it from an enlarged cervical lymph node. For this, draw an imaginary line bisecting the long axis of the ear to the angle of jaw. A cervical lymph node usually lies posterior to this imaginary line, while a parotid swelling overlies this line.

Differential diagnoses of a parotid swelling include suppurative parotitis caused by gram-positive bacteria like *Staphylococcus aureus*, gram-negative bacteria and nontuberculous mycobacteria. Suppurative parotitis is usually unilateral, extremely painful and may be accompanied by purulent discharge from Stensen's duct. Parotitis can also be caused by other viruses including parainfluenza types 1 and 3, influenza A virus, HIV, Epstein-Barr virus, enterovirus and cytomegalovirus. Mumps virus is the only known cause of epidemic parotitis. Noninfective parotitis is caused

by collagen vascular disorders (systemic lupus erythematosus, Sjögren syndrome), malignancies (leukemia, lymphoma), and obstruction of salivary gland duct due to calculus.

MANAGEMENT

Majority of the cases of mumps resolve spontaneously within 2 weeks without any significant complications or sequel. Thus the management is mainly supportive with the use of paracetamol for fever. Patients are advised to avoid sour food and drinks as they irritate the already inflamed salivary glands. Hot or cold packs may be applied locally under supervision to reduce inflammation. Warm salt water gargles, soft foods, and extra fluids may also help relieve symptoms. Sucking on lozenges that stimulate the salivary secretions helps in reducing the swelling. There is no specific antiviral therapy against mumps. Uncomplicated cases may be managed on outpatient basis. Patients should preferably be isolated and advised to follow droplet precautions for at least 5 days from the onset of parotitis.

Complications should be treated based on the presentation. For orchitis, testicular ultrasonography should be obtained; ice-packs must be applied locally to reduce swelling along with scrotal support. Anti-inflammatory agents might help in faster recovery of orchitis. Pancreatitis is managed by intravenous hydration and rigorous monitoring. Meningitis or encephalitis is managed symptomatically.

PREVENTION

Care of Contacts

Affected children should preferably be isolated and not allowed to go to school for 7–10 days after the onset of parotid swelling. Unlike measles, postexposure prophylaxis is not effective with mumps vaccine and there is no role of mumps immune globulin. Measles, mumps, and rubella (MMR) vaccine can be given after exposure to provide protection against future exposures and confer immunity against other two antigens. Immunization during the incubation period of the disease does not increase the risk of any complications.

Active Immunization

Mumps vaccine is a live attenuated vaccine and is available in India as part of the combined MMR vaccine. The minimum recommended potency is 1,000 median cell culture infectious doses (CCID₅₀) of virus. The shelf-life of the lyophilized vaccine is 1 year at 4–8°C. The reconstituted vaccine can be administered subcutaneously or intramuscularly in a dose of 0.5 mL. Once reconstituted, it should not be used after 4 hours. Most commonly, the vaccine consists of the Jeryl-Lynn strain. Other strains in use are Leningrad-3 (erstwhile Soviet states); Urabe (Japan, France, Italy), L-Zagreb (Croatia, India, Slovenia), and Rubini (Switzerland). The ideal age for vaccinating children is 15–18 months. The vaccine is administered in a dose of 0.5 mL subcutaneously. MMR can be given to individuals who are already immune to one or more component viruses of the vaccine.

The antibody levels induced by the vaccine are generally lower and less long lasting as compared to that following natural infection. The immunogenicity of the vaccine depends on the virus strain used with the majority of them resulting in seroprotection in more than 80% of the vaccine recipients. The antibody levels tend to fall with time; hence a second dose of mumps containing vaccine is being administered in many of the developed nations of the world and is being considered in regions with good vaccination coverage in order to avoid epidemic resurgence of the disease.

Adverse events to mumps vaccine are rare. Aseptic meningitis is reported in 0.1–100 per 100,000 vaccines. The vaccine is

contraindicated in pregnancy, history of anaphylactic reaction to egg, presence of immunodeficiency disorders, those receiving immunosuppressive drugs, and persons who have received immunoglobulins or blood transfusion recently in the past 3 months. For such patients, who cannot be vaccinated, it is advisable to vaccinate their close susceptible contacts (cocooning). Vaccine-virus is not transmitted by immunized persons.

MUMPS CONTROL STRATEGY

By the year 2000, approximately 120 countries or regions had included vaccination against mumps in their national immunization programs, mostly as MMR vaccine. Most countries in Africa and South-East Asia Region have not adopted this strategy and the incidence of mumps remains high in these territories. Only few states in India have incorporated MMR in their routine immunization schedule in a single dose between 15 months and 18 months of age.

Mumps infection can be controlled through high (more than 90%) routine coverage with MMR vaccine administered at 15–18 months of age. Following the trend observed in the developed countries, with the increasing routine vaccination coverage, a shift in the epidemiological profile of these diseases to a higher age group may not be ruled out in India. To avoid this there is a need to provide a second opportunity for immunization in regions with less than 80% coverage with the first dose. The catch-up immunization of susceptible cohorts may also be achieved targeting the vulnerable age groups in order to head toward mumps elimination.

IN A NUTSHELL

1. Mumps is a self-limiting, acute viral illness causing inflammation of parotid and other salivary glands.
2. The disease commonly occurs in the age group of 5–15 years. Natural infection with mumps virus confers life-long protection. The disease occurring in adults is more severe.
3. The mumps virus is transmitted through saliva or by respiratory droplets. The period of maximum infectivity is 2 days before till 5 days after the onset of parotitis.
4. The most common clinical presentation of the illness is parotitis (30–40%). The infection may be asymptomatic in 20–30% of cases.
5. Neurological manifestations are the most common extrasalivary manifestation of mumps infection. Other reported sites of infection are the testes, pancreas, eyes, ovaries, central nervous system, joints and kidneys.
6. The diagnosis is mainly clinical. History of exposure to a case of mumps would support the diagnosis.
7. The differential diagnosis of parotitis includes cervical lymphadenopathy, suppurative (bacterial) parotitis, viral parotitis and noninfective parotitis caused by collagen vascular disorders, malignancies and salivary gland calculus.
8. The management is mainly supportive. Spontaneous recovery occurs in 2 weeks in majority.
9. The disease can be prevented by administration of the mumps vaccine which is a very safe and effective vaccine and is available as a component of MMR vaccine.
10. Several countries have been able to reduce the incidence of mumps drastically after inclusion of MMR vaccine in two dose schedule in their national immunization program.

Chapter 31.5

Rubella

Pooja Dewan, Piyush Gupta

Rubella or German measles or third disease is usually a mild illness caused by the rubella virus. Rubella commonly affects children, though it can affect people of all age groups. Depending on the (acquired) age of presentation, rubella infection is categorized as *postnatal rubella infection* or *congenital rubella infection (CRI)*.

EPIDEMIOLOGY

Rubella is distributed worldwide. Man is the only host for rubella virus and there is no known animal reservoir. There is no true carrier state for rubella, though infected infants are known to shed the virus for extended periods. During the acute illness the rubella virus may be carried in the naso-opharynx, urine, stool, or cerebrospinal fluid. Rubella is contagious and transmission occurs by droplet spread and the virus multiplies in the oropharyngeal epithelium and regional lymph nodes. This is followed by a viremic phase lasting for 2 weeks. Viral shedding continues in the respiratory secretions, urine and stool. Postnatal rubella is infective from 7 days before to 14 days (median 5 days) after the appearance of rash. The maximum period of infectivity lasts from 7 days before until 7 days after the appearance of rash.

Congenital infection occurs by transplacental spread and the virus replicates extensively in the fetus. Infants with CRI can shed rubella virus in urine throughout infancy. Rubella virus can also be isolated from the lenticular aspirates during early childhood in infants with congenital rubella cataracts. Rubella infection in the fetus can lead to widespread tissue damage. The spectrum of organ damage in the infants includes the brain, heart, eyes, and auditory nerve. The exact mechanism of cellular injury is not clear, but ischemia, chromosomal breaks, and mitotic arrests could have some role.

Prior to the use of rubella vaccines, the disease occurred in epidemics affecting mainly children, occurring in 6–9-year cycles. With the introduction of rubella vaccines in 1970s and 1980s, most cases occurred in young unimmunized adults. Since then, rubella and congenital rubella syndrome (CRS) has decreased dramatically in the western hemisphere. The World Health Organization set goals for elimination of rubella and CRS in the WHO Region of the Americas by 2010 and European Region by 2015. Pan American Health Organization confirmed that the region of the Americas had achieved the rubella and CRS elimination goals in 2012. While the western hemisphere has managed success in its efforts to control CRS, most of the developing countries, including India, continue to grapple with the morbidities and long-term effects of CRS.

AGENT

Rubella virus is a single stranded RNA virus belonging to the genus *rubivirus* which belongs to the family *Togaviridae*. Humans are the only source of infection.

CLINICAL FEATURES

Postnatal/Acquired Rubella

Postnatal rubella is a mild disease similar to other viral illnesses in childhood. The incubation period for postnatally acquired rubella ranges from 14 days to 21 days, usually 16–18 days. Postnatal (or acquired) rubella infection is usually a mild febrile illness associated with rash and lymphadenopathy. Natural infection confers lifelong immunity. Most cases of postnatal rubella infection are often

subclinical. The disease in children is often milder and recovery is much faster than in adults. The usual presenting features include fever, rash, lymphadenopathy and arthralgia/arthritis.

The illness usually begins with mild febrile illness characterized by temperature of about 37.5–38.5°C. The other features commonly associated include running nose, coryza, headache, myalgia, and mild conjunctivitis. The rubella rash appears as either pink or light red spots on the face and neck, which may merge to form evenly colored patches. The rash spreads starting from face to the rest of the body. The rash can itch and lasts for 2–3 days. As the rash clears, the affected skin occasionally sheds in very fine flakes. On the first day of appearance of exanthem, small pink-colored ring lesions and petechiae also appear on the soft palate known as *Forchheimer spots* (pathognomonic of rubella infection). Tender and enlarged lymph nodes usually involving the suboccipital and postauricular group of lymph nodes, lasting 5–8 days are also seen. Lymphadenopathy may precede the rash. Polyarthralgia and polyarthritis seen in rubella is usually transient. It is rarely seen in children but is common in adolescents and adults, especially females. Other complications like thrombocytopenia, encephalitis, myocarditis and Guillain-Barré syndrome are rarely seen.

Congenital Rubella Infection

Maternal rubella infection during pregnancy can result in fetal infection by transplacental spread. Fetal rubella infection can in turn result in miscarriage, fetal death, or a spectrum of multisystem abnormalities in the infant referred to as the CRS. Teratogenic effects of maternal rubella infection can be seen in up to 90% of neonates and infants if maternal infection occurs during the first 12 weeks of gestation. This reduces to about 25% and 11%, if maternal infection occurs during the 13–14 weeks of gestation and 15–16 weeks, respectively. Maternal infection after the 16th week has a low risk for teratogenic effects in fetus. The infected infant may be symptomatic in the neonatal period (early onset disease) and develop evidence of CRS subsequently (late onset disease). **Table 1** depicts the spectrum of anomalies seen in CRS which may present early or late.

DIAGNOSIS

Rubella-specific IgM antibodies usually indicate recent postnatal infection or congenital infection in a newborn infant. Rubella antibodies (IgM) can be detected by 5th day of acquired rubella. For diagnosis of postnatally acquired rubella, a fourfold or greater increase in antibody titer or seroconversion between acute and convalescent IgG serum titers also indicates infection.

Most congenital rubella cases are IgM-positive at birth up to 3 months of age. Rising rubella-specific IgG titers in blood

Table 1 Clinical features of congenital rubella syndrome

Early onset disease	<i>Ophthalmologic:</i> Cataracts (Fig. 1), glaucoma, pigmentary retinopathy, microphthalmia <i>Cardiac:</i> Patent ductus arteriosus, pulmonary stenosis or septal defects <i>Neurological:</i> Microcephaly, behavioral disorders, meningoencephalitis, mental retardation <i>Auditory:</i> Sensorineural deafness <i>Others:</i> Hepatosplenomegaly, thrombocytopenia, dermal erythropoiesis (blue-berry muffin rash, Fig. 2), radiolucent bone disease, and intrauterine growth retardation
Late onset disease	<i>Ocular abnormalities:</i> Cataract, glaucoma, retinal detachment <i>Endocrinal disorders:</i> Diabetes mellitus, thyroid dysfunction <i>Psychomotor defects</i>

Figure 2 This infant presented with *blueberry muffin* skin lesions indicative of congenital rubella. Such lesions represent sites of extra-medullary hematopoiesis, and can be associated with several different congenital viral infections and hematologic diseases. The rash and fever last for 2–3 days. The illness is mild in children and young adults
Source: Public Health Image Library (PHIL), CDC, USA.

during the first 7–11 months of life also suggest CRI. Diagnosis of CRI beyond infancy is difficult and may be tried by viral cultures from tissue samples including throat and nasal specimens or lens aspirates. Detection of rubella virus RNA by reverse-transcriptase polymerase chain reaction, followed by genotyping of strains can aid epidemiology.

DIFFERENTIAL DIAGNOSIS

Several febrile illnesses with rash can present with similar clinical features and hence the diagnosis of rubella can be challenging. Conditions to be considered in the differential diagnosis of rubella are detailed in **Table 2**.

TREATMENT

Treatment of acquired rubella infection is only supportive. Acetaminophen can be given for fever.

PROGNOSIS

The prognosis for acquired rubella is generally excellent. Rubella infections usually clear within 2–3 weeks and also provide lifelong immunity against the virus. However, pregnant women infected with rubella have a spontaneous abortion rate of about 5% and a stillborn rate of 1–2%. Prognosis for the infected neonate depends on the extent of damage. Severely affected infants can have mortality rates of up to 20% in the first year of life. Mothers infected in the first month of pregnancy deliver neonates with serious permanent damage in 50% of such cases. Sequelae in early childhood include growth retardation during preschool years, microcephaly, cataracts, deafness and congenital heart disease. In teenage and early adult life thyroid disorders develop in 5% of survivors. About 20% of them develop diabetes by the third decade of life. Panencephalitis is a delayed and dreaded complication of CRS. Long-term outcomes of CRS are variable and survivors with malformations have to cope with medical, social, emotional and economic handicaps.

PREVENTION AND CONTROL

Isolation of infected individual is recommended to prevent spread of illness to others. For individuals affected with postnatal rubella, droplet precautions are recommended till up to 7 days after onset of the rash. For children with proven or suspected congenital rubella, isolation is recommended until they are at least 1 year of age, or unless two cultures of clinical specimens obtained 1 month apart after 3 months of age are negative for rubella virus.

Active Immunization

Childhood rubella is a mild clinical illness and hence does not necessitate routine prophylaxis; immunization is necessary only to prevent CRS. There are several approaches which have been used in different countries to eliminate CRS:

- Immunization of infants and young children
- Immunization of adolescent females and/or women of childbearing age
- Immunization of adolescent males and females
- Immunization of infants and adolescent girls and adult women (best approach)
- Immunization of hospital personnel.

Each of the above approaches has their own limitations which may hamper complete elimination of CRS. *Selective immunization of adolescent girls and/or women of childbearing age* alone may be inappropriate as unvaccinated girls (e.g., those who refuse vaccination) will still be exposed to circulating rubella virus in male population and children. Universal immunization of infants and young children of both sexes will reduce the circulation of virus. However, pregnant women would still continue to be exposed to rubella in adults. It is now realized that combining universal immunization of infants and children with vaccination of adolescent girls and adult women is the most effective approach to eliminate rubella and CRS.

The Vaccine

The first rubella vaccine was licensed for use in 1969. Most of the currently licensed vaccines are based on the live, attenuated RA27/3 strain of rubella virus, propagated in human diploid cells. Each dose of this vaccine contains a defined number of active virus particles (> 1,000 TCID₅₀). Other attenuated rubella vaccine strains, such as the Matsuba, DCRB 19, Takahashi, Matsuura, TO-336 and BRD-2 strains are used in Japan and China.

The rubella vaccine is usually offered as a live attenuated virus, usually given as part of combination vaccines like MMR vaccine (protecting against measles, mumps, and rubella) or

Table 2 Differential diagnosis of acquired rubella infection

Scarlet fever	Rash appears on the second day of illness characterized by fine red points on an erythematous background. The flexural surfaces may have hemorrhagic staining. Sore throat and enlargement of lymph nodes below the ear are common features. Strawberry tongue is seen. Eyes are usually not congested or watery. The rash takes several days to fade and as the rash fades a dark punctuate discoloration may be seen on shoulders or bends of elbows. Rash may be associated with peeling of skin.
Measles (rubeola)	Headache, malaise, and coryza are seen on the first day. Fever may be high grade and child may be listless and toxic. Koplik spots appear on the second day while the rash comes out late on the third day. The eyes are usually catarrhal (conjunctivitis). Tongue may be dry and furred. In measles a blotchy mottling on the parts where the rash has been is seen and it may persist for a few days after the illness and is described as postmeasles staining.
Kawasaki disease	Prolonged fever associated with constellation of clinical features like conjunctivitis, erythematous swelling of hands and feet, cervical lymphadenopathy, oropharyngeal lesions, and uveitis. Rash is polymorphous and may be localized to extensor aspects of lower limbs and groin. Coryza is usually absent.
Exanthem subitum	Rash appears on the fifth day of fever. Rash is usually discrete maculopapular starting from trunk and spreading to face and extremities. Illness is accompanied by irritability and occipital lymphadenopathy. Rash does not peel.
Erythema infectiosum	Usually no prodromal symptoms are seen. Cheeks appear red and indurated. The rash is symmetrical, maculopapular, confluent, and over the extensor face of upper and lower limbs. Rash does not peel.
Enteroviral infections	Prodromal period (usually 3–5 days) is seen. Rash is maculopapular discrete, nonitchy and generalized. Rash is not associated with peeling. Aseptic meningitis may be seen.
Infectious mononucleosis	A prolonged prodromal illness. Pleomorphic rash usually preceded by intake of ampicillin. There is associated hepatosplenomegaly, membranous tonsillitis, and lymphadenopathy. Rash is not associated with desquamation.
Drug reactions	Confluent maculopapular rash which may be seen with fever and mild constitutional symptoms. There is usually a history of drug intake prior to the appearance of symptoms.
Dengue fever	Seen in patients with a history of recent travel to an endemic region during the rainy season. It presents with an influenza-like profile with a maculopapular morbilliform or scarlatiniform rash. The illness may be complicated by bleeding and shock.

MMRV vaccine (protecting against measles, mumps, rubella and varicella) in children. The immune response to rubella antigens is not affected by the other vaccine components. It may be given as a monovalent vaccine, i.e., rubella vaccine (alone) or as bivalent MR (protecting against mumps and rubella) in adolescents and adults.

Dosage

The rubella containing vaccines (RCVs) are given either subcutaneously or intramuscularly. In children two doses of MMR vaccine are recommended; first dose at 12–15 months (not earlier as the maternal antibodies can persist up to 12 months) and the second dose when the child is 4–6 years old. A single dose of MMR administered after infancy provides adequate protection till 5 years age. However, a second dose given at 4–6 years offers 95–100% protection. All older children (≤ 12 years) should receive at least one dose of rubella vaccine. Vaccine-induced immunity is generally lifelong.

Adverse Reactions

Adverse reactions to rubella vaccine include fever (5–7 days after vaccination in 5–15% of recipients), lymphadenopathy, arthritis/arthralgia of peripheral joints, and transient skin rash, all of which are self-limiting. Joint involvement usually begins 7–21 days after immunization and generally is transient. The incidence of joint manifestations after immunization is lower than that after natural infection at the corresponding age. Previously, rubella vaccine was believed to be associated with Guillain-Barré syndrome, autism, ulcerative colitis and aseptic meningitis, all of which have been now refuted.

Contraindications

Pregnancy is an absolute contraindication for rubella vaccination. Also, any woman who receives a RCV should not conceive within 28 days of receiving the vaccine (CDC). Persons receiving blood products (except washed red cells) or immunoglobulins should not receive RCV up to 3–12 months after receiving the transfusion. Immunocompromised states like those receiving cancer chemo-

therapy or high doses of steroids (2 mg/kg or greater or more than 20 mg/day) for 14 days or more are also contraindications for rubella vaccination. Persons with serious allergies to gelatin or components of vaccine should refrain from receiving RCV. Persons with HIV infection but no AIDS can receive RCV.

Postexposure Prophylaxis

If a pregnant mother is suspected of having been exposed to possible rubella during early pregnancy, a blood specimen should be obtained as soon as possible and tested for rubella antibody (IgG and IgM). An aliquot of serum should be stored for possible repeated testing at a later time. The presence of rubella-specific IgG antibody in a properly performed test at the time of exposure indicates that the person most likely is immune. If antibody is not detectable, a second blood specimen should be obtained 2–3 weeks later and tested concurrently with the first specimen. If the second test result is negative, another blood specimen should be obtained 6 weeks after the exposure and also tested concurrently with the first specimen; a negative test result in both the second and third specimens indicates that infection has not occurred, and a positive test result in the second or third specimen but not the first (seroconversion) indicates recent infection. If the infection is confirmed (mothers with IgM positive or rising IgG titers), medical termination of pregnancy may be advised.

SURVEILLANCE

Methods for surveillance of CRS include hospital record review, deaf/blind surveys, clinician reporting, and active search for cases with CRS after outbreaks of acquired rubella. Serological surveillance among antenatal women can be used to monitor the impact of the immunization program. The WHO has established a Measles-Rubella Laboratory Network (LabNet) in 2002 which comprises of a total of National Reference Laboratories supervised by Regional Reference Laboratories to enable high quality laboratory surveillance of suspected rubella and CRS cases worldwide.

IN A NUTSHELL

1. Rubella is usually a mild exanthematous illness caused by the rubella virus affecting humans worldwide.
2. Man is the only host for rubella virus and there is no known animal reservoir.
3. The illness is characterized by mild fever, rash, arthralgia, and lymphadenopathy. Fetal rubella infection due to transplacental spread from affected mothers result in miscarriage, fetal death, or a spectrum of multisystem abnormalities in the infant referred to as the CRS.
4. Congenital rubella syndrome is characterized by a triad of sensorineural deafness, ophthalmologic and cardiac abnormalities.
5. Rubella can be eliminated.
6. Active immunization of children, adolescent females, and women in reproductive age group with RCVs and active surveillance is recommended to decrease CRS burden.

Chapter 31.6

Varicella

Piyush Gupta, Aashima Dabas

Varicella (chickenpox) is a highly infectious disease caused by primary infection of varicella-zoster virus (VZV). The illness is characterized by an exanthematous vesicular rash with a centripetal distribution. The rash typically begins as maculopapular lesion on first day of fever. The course is usually benign and lasts for about 7 days. Chickenpox infections give lifelong immunity. However, VZV can remain latent and activate years later as herpes zoster (shingles). Primary disease causes substantial morbidity but is vaccine preventable.

EPIDEMIOLOGY

The virus infects only primates and man is the only reservoir. All age groups can be infected with predisposition for younger ages. Since the introduction of varicella immunization in developed countries, the infection prevalence is more during later school years than preschool age. The disease usually occurs during hot temperate climate season. Immunocompromised patients, infants and adults are more prone to develop serious disease.

AGENT

Varicella-zoster virus is an enveloped DNA virus of the Herpes virus family. Three major genotypes of the virus (Japanese, European, and Mosaic) are identified, but only one serotype is known. The wild VZV and the vaccine-derived VZV can be distinguished by restriction enzyme analysis of genome. The virulence of wild-VZV is due to the glycoproteins produced during viral replication. These glycoproteins contribute to structure of virions, are antigenic, and promote adhesion and entry of VZV into uninfected cells.

TRANSMISSION

Varicella virus is transmitted from a varicella patient to others mainly by direct contact from skin lesions. In addition, the airborne route also contributes to VZV spread as VZV has been detected by polymerase chain reaction (PCR) in nasopharynx of children during pre-eruptive stages of the infection. Crusts from chickenpox lesions do not contain live virus. Infectivity is therefore maximum during prodromal period and wanes off when eruptions become crusted. Period of infectivity ranges from 48 hours prior and up to 3–7 days after the rash appears. The lesions of herpes zoster also contain infectious VZV and are contagious, though less contagious than varicella eruptions. Varicella is known to occur after exposure to a patient with zoster. Zoster, *per se*, is not acquired by contact with a patient with varicella or zoster. It occurs in states with depressed cell-mediated immunity due to reactivation of VZV multiplication in the body.

Varicella virus is transmitted to 65–86% of susceptible household contacts. This secondary attack rate is lower in a school setting. A single exposure to varicella is sufficient to result in lifelong immunity to VZV and second attacks of varicella are rare (may occur in immunocompromised). Zoster is unusual in children less than 10-year-old but may occur if chickenpox is acquired in early infancy. The lifetime risk for a person to develop zoster after history of varicella is 10–20%.

PATHOGENESIS

Airborne virus enters the oropharynx through inhalation by droplet infection. Primary seeding occurs in tonsillar tissue and mucosa of the upper respiratory tract. Virus replication for initial

10 days is followed by primary viremia that spreads the virus to reticuloendothelial system. No clinical symptoms occur during this primary low-grade viremic phase. Skin lesions appear only during the secondary viremic phase that lasts for 3–7 days. Infectious virus is carried to vesicular fluid and also back to respiratory mucosa, from where it is shed, transmitting infection to susceptible contacts. Alternately, VZV may reach the keratinocytes directly by virus-infected CD4 memory T-cells. VZV may be transported to the dorsal root of spinal cord, where a latent infection is established. Reactivation of this focus at a later stage results in herpes-zoster.

The cell-mediated immunity acts as chief defense with contribution from humoral immunity. Natural killer cells and antibody-dependent cell cytotoxicity are also implicated in defense. The cell-mediated immune reactions remain positive for many years and IgG antibody to VZV may be detectable for decades in adults after recovery. Despite presence of adequate cell-mediated and humoral immunity, few people may still develop milder clinical illness following exposure to wild VZV (*breakthrough varicella*).

The histological changes in skin are similar to both varicella and zoster with the presence of multinucleated giant cells with intranuclear inclusions in the epidermis and dermis. There is accompanying intercellular edema which separates the skin layers to result in a vesicle. In zoster, in addition to above, an inflammatory infiltrate is present in dorsal root ganglion of the affected dermatome.

CLINICAL FEATURES

Chickenpox occurs at all ages (including neonates) with peak incidence between 2 years and 8 years. The median incubation period is 14–16 days (range 10–21 days). The disease ushers in with fever and malaise. Prodromal symptoms also include headache, sore throat, and backache. Prodromal symptoms are frequent in adults but may be absent in children where rash may be the only presenting symptom. The rash appears within 24 hours of the onset of prodrome. Fever is usually moderate, usually between 38.8°C (102°F) and 39.4°C (103°F), but may rise to 41.1°C (106°F). Fever usually resolves after 3–4 days of appearance of rash.

Evolution of the Rash

The rash begins as crops of macules, which evolve into papules and then vesicles. The vesicles are initially filled with clear fluid that soon becomes cloudy. The vesicles persist for 3–4 days, become pustular and then form crust. The vesicles may be round, oval, elliptical or irregular, often surrounded by red areola. The lesions first appear over face, scalp, or trunk, and then spread to whole body. Palms and soles are spared. The lesions measure 5–10 mm in diameter. New lesions may keep occurring over 1 week. Most children have more than 250 lesions. Macules, papules, vesicles and scabs can be seen simultaneously. Lesions tend to be more abundant on covered than exposed parts of the body. By the time of vesicle formation, there is excessive itching. Vesicles may also be observed over conjunctiva, palate, tongue, and buccal mucous membranes. Vesicles dry up within 1–2 days, starting from the center, forming crusts and scabs. Scabs fall off in 10–20 days. Underlying skin becomes hypo- or hyperpigmented that stays for days to weeks. Permanent scarring is unusual.

Subclinical varicella is rare, but few adults with no prior history of disease or vaccination to VZV may show detectable antibodies to VZV.

COMPLICATIONS

Bacterial Infections

Secondary skin infection due to Group A *Streptococcus* and *Staphylococcus aureus* results in cellulitis, erysipelas, and

skin abscesses. Bacteremic spread may lead to pneumonia, osteomyelitis and septic arthritis.

Neurological Complications

Neurological complications occur towards the end of first week of illness as the rash reaches maturity. The most common manifestation is a pure cerebellar ataxia which has an excellent prognosis. Meningoencephalitis is a dreaded complication with 5–25% mortality. Acute disseminated encephalomyelitis (ADEM) is a rare form of postvaricella encephalitis with cerebral demyelination. It presents with cranial nerve involvement, long tract signs, and convulsions. Transverse myelitis, acute infantile hemiplegia, and Guillain-Barré syndrome are the other neurological complications. Chronic neurological sequels are rare.

Pneumonitis

Varicella pneumonia appears 3–5 days after the onset of rash. These children present with acute respiratory distress and hemoptysis and diffuse nodular infiltration in chest radiograph.

Others

Myocarditis, pericarditis, endocarditis, hepatitis, glomerulonephritis, appendicitis, keratoconjunctivitis, arthritis, thrombocytopenia, and purpura fulminans are the other notable complications. Immunocompromised children infected with HIV may develop chronic wart like lesions of VZV due to low grade persistent infection.

DIAGNOSIS

The diagnosis of varicella is essentially clinical. The rash of chickenpox needs to be differentiated from other causes of vesicubullous rash: (1) infections with herpes simplex, rickettsia, infected scabies, *S. aureus*; and (2) noninfecting conditions including contact dermatitis, drug reactions and insect bites. Routine laboratory investigations are not essential. Leukopenia is typical during the first 72 hours, followed by lymphocytosis. Liver enzymes may be mildly elevated.

- **Rapid laboratory diagnosis** can be made by electron microscopy or by immunofluorescence. VZV can be identified by direct fluorescence assay of cells from the vesicles or by PCR amplification testing. Presence of multinucleated giant cells on Tzanck smear is nonspecific. The virus may also be detected by PCR from the respiratory secretions or cerebrospinal fluid.
- **Virus isolation and culture methods** are successful only when done early in the disease course. Isolation of VZV is difficult from dry or crusted skin lesions. Viral culture, however, is time taking and not routinely performed.
- **IgG antibodies** to VZV can be detected by latex agglutination or enzyme-linked immunosorbent assay. A fourfold rise in antibody titer in acute and convalescent sera, or raised IgM-VZV antibody level in a single sample, is confirmatory of acute infection.

TREATMENT

Supportive Therapy

No treatment is usually required and bed rest is unnecessary except in ill children. Paracetamol usually controls prodromal symptoms and fever. Aspirin should not be given because of the risk of Reye syndrome. Calamine lotion will normally soothe pruritus; if not, an antihistaminic should be tried. If the enanthem is severe, careful oral toilet is needed. Lesions on the conjunctiva should be protected from secondary infection.

Specific Therapy

Acyclovir therapy is not recommended routinely for treatment of uncomplicated chickenpox in the otherwise healthy child because of marginal benefit, cost of the drug and low risk of complications of the disease. Oral acyclovir to healthy children within 24 hours of onset of rash decreases the duration of rash by 1 day and number of new lesions by only 25%.

Indications for acyclovir in varicella infection are as follows:

- Chronic cutaneous or pulmonary disorders
- Those receiving short-term, intermittent or aerosolized corticosteroids
- Those receiving long-term salicylate therapy
- Immunocompromised patients including those with HIV infection and malignancies and
- Disseminated varicella infection including pneumonia, encephalitis, severe hepatitis, or thrombocytopenia.

Intravenous acyclovir therapy is indicated for severe disease and for varicella in immunocompromised patients. Intravenous acyclovir (10 mg/kg or 1,500 mg/m² q 8 hours IV) initiated within 72 hours of development of initial symptoms decreases the progression of the disease in high risk patients. The treatment is continued for 7–10 days. The drug should be administered as an infusion and creatinine clearance should be monitored. Oral acyclovir (20 mg/kg/dose) given as 4 doses/day for 5 days should be used for the other indications mentioned above. Treatment should be initiated as early as possible, within 24 hours of rash and preferably not beyond 72 hours. The therapy is continued for 7–10 days or till no new lesion appears for 48 hours (**Table 1**).

Children with herpes-zoster generally have milder self-limited disease with minimal postherpetic neuralgia. Thus oral acyclovir may be reserved for use in healthy children who complain of severe pain or in immunocompromised children. The drug dosage and duration is the same as above.

Foscarnet (60–90 mg/kg/day) is the only available drug for acyclovir-resistant varicella. Experience with valacyclovir (prodrug of acyclovir) and famciclovir (prodrug of penciclovir) is limited in children.

Cloxacillin can be used to treat skin infections. More severe sepsis will require appropriate antibacterial chemotherapy which should be guided by swabbing of the affected lesions and by cultures of the blood and of any pus. Corticosteroids have no role in treatment of zoster.

Table 1 Acyclovir for treatment of varicella in immunocompetent children

Age group	Uncomplicated	Complicated*
Neonates	Intravenous acyclovir (10 mg/kg/dose), thrice a day. <i>Duration</i> : 14 days for skin/eye involvement, to 21 days for disseminated or CNS disease	
Infants (0–1 year)	Oral acyclovir (20 mg/kg/dose) given as four doses/day for 7–10 days	Intravenous acyclovir (10 mg/kg/dose or 1,500 mg/m ² q 8 hours IV) for 7–10 days
Children (1–13 years)	No antivirals	
Adolescents (> 13 years)	Oral acyclovir (20 mg/kg/dose) given as 4 doses/day for 7–10 days	

* Disseminated varicella infection including pneumonia, encephalitis, severe hepatitis, or thrombocytopenia.

PREVENTION

Active Immunization

Two doses of live virus vaccine (administered at 12–15 months, and 4–6 years) are recommended by the Indian Academy of Pediatrics to prevent varicella in healthy children. Protective efficacy of two-dose regimen is 98–100%. Varicella vaccine should not be given within 4 weeks of MMR vaccination; however, both can be given simultaneously.

Postexposure Prophylaxis

Varicella vaccine, if given within 3–5 days of exposure, can prevent or modify the disease in household contacts. Chemoprophylaxis with acyclovir is not an established mode of prevention.

Varicella zoster immunoglobulin (VZIG) 125 unit (U) is recommended for newborns whose mothers have varicella 5 days before to 2 days after delivery. Other susceptible high risk contacts (pregnant women, immunocompromised children, and those with malignancy or on steroids) should also be given VZIG (125 U for every 10 kg increment, to a maximum of 625 U).

HERPES ZOSTER

This condition represents reactivation of a latent VZV infection and occurs several years after primary infection with VZV and is less common in children. It is characterized by localized unilateral painful vesicular eruptions over 1–3 dermatomal segments (**Fig. 1**). The skin lesions are more pruritic and painful than varicella, though pain and severity is less in children as compared to adults. Some immunocompromised patients may experience protracted pain after healing of skin lesions (postherpetic neuralgia). They may have disseminated lesions mimicking varicella, pneumonia, hepatitis, or encephalitis. Severely affected HIV patients may develop a chronic relapsing cutaneous disease or central nervous system disease without rash. Around 4% patients may suffer a repeat episode of zoster. Subclinical zoster may also occur with dermatomal pain but no rash (*zoster sine herpette*).

PROGRESSIVE VARICELLA

Certain patients (immunocompromised patients, pregnant women or newborns) may experience a severe disease when fever and rash progression may continue for more than 2 weeks. Severe disease can be life-threatening, if associated

with disseminated intravascular coagulation or visceral organ dysfunction. Ominous signs include severe abdominal pain (involvement of mesenteric lymph nodes or liver) or appearance of hemorrhagic vesicles.

CONGENITAL VARICELLA

This is a constellation of defects which occur due to maternal VZV infection during first or second trimester, first described by LaForet and Lynch in 1947. There is a 2% risk to the baby for developing congenital varicella embryopathy following maternal infection in early gestation. Though most cases occur following maternal varicella, a small proportion is reported after maternal herpes-zoster infection. The hallmark of the disease is cicatricial scarring of the limbs—characterized by zigzag scarring of skin in dermatomal pattern with limb hypoplasia. The embryopathy is associated with (1) neurological features—cortical atrophy, microcephaly, seizures, mental retardation; (2) eye abnormalities—retinitis, microphthalmia, cataract; (3) digital defects, and (4) renal anomalies in few. The diagnosis is predominantly clinical and supported by historical clues. Viral DNA identification by PCR from tissue samples may be done; serology is not conclusive. There is no prophylactic role of varicella immunoglobulin or acyclovir administration to mother in antenatal period. Treatment of the newborn with acyclovir (after delivery) is not effective.

VARICELLA NEONATORUM

This condition results when a neonate born to mother with varicella infection acquires clinical varicella in the first few days after birth. If maternal rash develops more than 5 days before delivery, the virus may still be transmitted to the fetus, but clinical disease does not occur in the newborn due to simultaneous transfer of maternal VZV antibody (seen only after 30 weeks gestation). If the maternal rash appears less than 5 days before delivery or up to 2 days after delivery, there is 17–30% risk that the baby will receive a large inoculum without maternal antibody. Such babies are at a very high risk of disseminated disease with death (fatality rate can be as high as 30%, if not treated in time) from pneumonitis, and should be protected at birth by giving VZIG. In addition, all preterm less than 28 weeks with active maternal varicella during delivery should also receive VZIG. Neonatal varicella may still occur in 50% of these, despite VZIG administration; however, the disease is mild. If symptoms develop, the baby should receive acyclovir (10 mg/kg q 8 h) for 7–10 days. A neonate can also acquire varicella postnatally from the community and should also be treated with acyclovir. VZIG has no role once active infection has occurred.

BREAKTHROUGH VARICELLA

Varicella vaccine administered as a one-dose regimen to healthy children offers 85% protection (range 44–100%). Vaccinated children can thus suffer from varicella. Breakthrough varicella is defined as varicella occurring in a child who was vaccinated at least 42 days prior to eruption of the rash with one dose of varicella vaccine, and caused by wild type varicella virus. Rash occurring between 14 days and 42 days after vaccination can also be due to vaccine strains.

Breakthrough varicella is usually a mild disease (25% may still have florid rash). It is predominated by a maculopapular rash; vesicles are less frequent. Number of lesions is less than 50. These children are less likely to transmit the disease to others, i.e., the secondary attack rate of breakthrough varicella is lower than classical varicella. Recipients of two-dose varicella vaccine are less likely to have breakthrough varicella as compared to those having received one dose only.

IN A NUTSHELL

1. Chickenpox is caused by primary infection of VZV; reactivation, years later, results in zoster. Both varicella and zoster are highly contagious.
2. Man is the only reservoir. Natural infection provides lifelong immunity.
3. The typical varicella rash is pleomorphic, vesiculopustular and distributed in a centripetal pattern.
4. Period of infectivity ranges from 48 hours before the onset of rash till lesions have crusted (4–5 days).
5. Diagnosis is clinical; there is no role of laboratory investigations in routine diagnosis of chickenpox.
6. Disease is more severe in less than 1 year and more than 13 years age, and immunocompromised children.
7. Antiviral drugs are not routinely indicated for uncomplicated varicella in children 1–13 years age.
8. Acyclovir is used only in immunocompromised, neonates and complicated cases (meningoencephalitis, ataxia, ADEM, pneumonitis or other systemic complications).
9. Immunoprophylaxis with live attenuated vaccine is recommended for susceptible household contacts within 4 days of exposure. There is no role of chemoprophylaxis.
10. Neonates born to mothers, who develop varicella 5 days before or 2 days after delivery should receive 125 U of VZIG.

Chapter 31.7

Parvovirus Infections

Jagdish Chandra, Anu Maheshwari

Human parvovirus B19 (B19) belongs to the *Erythrovirus* genus within the Parvoviridae family. This virus was first discovered in 1975 while routine screening of asymptomatic donors for hepatitis B virus. The clinical implications of this virus were noted in 1981. Sample 19 in panel B (hence the name parvovirus B19) was read as a false positive result on a counterimmunoelectrophoresis assay. B19 is the predominant parvovirus pathogen in humans. The B19 strain is the prototype strain for genotype 1. The other less common and more recently described erythroviruses infecting humans include genotype 2 (prototype strain, LaLi) and genotype 3 (prototype strain, V9). Genotypes 1 and 2 are typically found in western countries (e.g., USA and Europe), while genotype 3 is found primarily in sub-Saharan Africa and South America, but is spreading.

EPIDEMIOLOGY

Parvovirus B19 infection occurs worldwide. Cases may be sporadic or can occur in clustered outbreaks. Where reportable, communities have documented not only a seasonality to B19 infections, but also cycles of local epidemics with case numbers that can peak every 4–10 years. The percentage of people with measurable levels of B19-specific IgG increases with increasing age, with most individuals becoming infected during their school years. When considering women as a separate group, approximately 30–40% of pregnant women lack measurable IgG to B19 and are therefore presumed to be susceptible to B19 infection.

AGENT

Parvovirus B19 is a small (26 nm), nonenveloped, ssDNA (5.6-kb) virus. The only known host for B19 is humans. The virus replicates in erythroid progenitor cells (late erythroid cell precursors and burst-forming erythroid progenitors) of the bone marrow leading to inhibition of erythropoiesis, which can result in anemia. The observed tropism of parvovirus is most likely due to the distribution of its cellular receptor, P blood group antigen. It is a globoside, which is found in high concentrations on red blood cells and their precursors. Rare individuals who lack P antigen are resistant to infection with parvovirus.

TRANSMISSION

Infected patients are most contagious during the phase of active viral replication and viral shedding, which occurs approximately 5–10 days after the exposure. During this phase, patients can be asymptomatic or present with nonspecific flu-like illness. It is not until the second phase of parvovirus infection that a person can present with specific symptoms or signs (e.g., arthralgia, arthritis, and/or an exanthem) specific to B19 infection. This is also the phase in which B19-specific antibody production and B19 antigen-antibody immune complex formation occurs. Individuals are no longer infectious when exhibiting these clinical characteristics. Patients having weakened immune systems may be contagious for a longer amount of time. There are three documented modes of transmitting B19:

1. *Respiratory transmission* is the most common way an individual acquires this virus. It is transmitted through close person-to-person contact, fomites, and respiratory secretions and/or saliva. Young children are the main source of respiratory acquired B19. This scenario places pregnant women with young children at home at high risk of becoming infected.

2. *Vertical transmission* can occur if a susceptible woman becomes infected during her pregnancy. The risk of a poor outcome for the fetus is greatest when the congenital infection occurs within the first 20 weeks of gestation.
3. *Transmission* can occur from transfusion of blood or blood products containing B19 (transfusion transmitted). Individuals requiring regular infusions of blood product(s) that are made from large plasma pools (albumin, IVIG) are at greatest risk for acquiring the virus compared to those individuals receiving single units.

PATHOGENESIS

Viremia occurs 7–10 days after exposure to the source and usually lasts approximately 5 days. The virus titer peaks in the first few days of infection and can reach or exceed 10^{12} particles per mL of blood. Parvovirus B19-specific IgM antibodies are detected as early as day 10–12 of illness and can persist for up to 5 months. Specific IgG antibodies are detectable about 15 days postinfection and persist long-term. The close timing that exists between developing B19-specific IgM and IgG antibodies means that it is rare to find an IgM-positive serum sample that is not also IgG-positive. Antibodies to VP1 are required for an effective immune response. The humoral antibody response is the major pathway that is responsible for virus clearance and subsequent protection from disease.

Parvovirus B19 infection also elicits an inflammatory cell-mediated immune response, including the production of tumor necrosis factor (TNF)-alpha, interferon (IFN)-gamma, interleukin (IL)-2 and/or IL-6. A striking CD8 T cell response was maintained and eventually increased over several months after the resolution of illness. The importance of cellular immunity is also suggested by clinical reports of remission of parvovirus induced anemia after initiation of highly active antiretroviral therapy in advanced AIDS patients.

CLINICAL FEATURES

The clinical presentations associated with B19 infection vary greatly, ranging from benign to life threatening (**Table 1**). The clinical presentation is influenced by the infected individual's age and hematologic and immunologic status. There are five well-established syndromes associated with B19 infection: (1) Fifth disease; (2) Arthropathy; (3) Nonimmune hydrops fetalis, intrauterine fetal death, or miscarriage; (4) Transient aplastic crisis in those with chronic hemolytic disorders; and (5) Chronic pure red blood cell aplasia (B19PRCA) in immunocompromised individuals. A wide range of other syndromes have been reported to be associated with B19 infections, but a causal role for the virus has yet to be conclusively established (**Table 2**).

Erythema Infectiosum

Erythema Infectiosum (EI) often occurs in outbreaks among school-aged children, although it can occur in adults as well. EI is also referred to as *fifth disease* since it represents one of six common childhood exanthems, each named in order of the dates they were first described. The illness begins with nonspecific prodromal symptoms, such as fever, coryza, headache, nausea, and diarrhea. These constitutional symptoms coincide with onset of viremia. Two to five days later, the classic erythematous malar rash appears (the so-called slapped cheek rash) with relative circumoral pallor. This facial rash (**Fig. 1**) is often followed by a reticulated or lacelike rash on the trunk and extremities (**Fig. 2**). The estimated incubation period from exposure to the onset of rash has usually been between 1 and 2 weeks but can be as long as 3 weeks. By the time the rash develops, viremia has resolved and the child usually feels well. The rash is thought to be immunologically mediated. A typical feature of EI is recrudescence of rash after a variety of nonspecific stimuli,

Table 1 Symptoms and signs of parvovirus B19 infection in children

Symptoms or sign	Frequency (%)
Fever	14–53
Headache	12–53
Sore throat	12–60
Pruritus	0–>50
Cough	5–40
Diarrhea	0–40
Nausea/vomiting	0–33
Coryza/conjunctivitis	4–27
Arthritis/arthritis	0–9

Table 2 Conditions associated with parvovirus infection

Cardiovascular
• Acute heart failure
• Myocarditis
• Pericarditis
• Pericardial effusion
Cutaneous
• Gianotti-Crosti syndrome
• Papular-purpuric gloves and socks syndrome
• Vascular purpura
• Erythema nodosum
• Erythema multiforme
• Livedo reticularis
Hematological
• Aplastic anemia
• Autoimmune hemolytic anemia
• Chronic neutropenia
• Thrombocytopenic purpura
• Transient erythroblastopenia of childhood
Neurological
• Brachial plexus abnormalities
• Meningitis/encephalopathy
• Seizures
• Sensorineural abnormalities
Rheumatological
• Vasculitis
• Juvenile idiopathic arthritis
• Systemic lupus erythematosus
• Rheumatoid arthritis
Renal
• Proliferative glomerulonephritis
• Collapsing nephropathy
• Post-transplant anemia, pancytopenia
• Nephrotic syndrome in sickle cell disease

such as change in temperature, exposure to sunlight, exercise, or emotional stress.

B19 infection has also been associated with other types of rashes including morbilliform, confluent, and vesicular rashes. In the Gianotti-Crosti syndrome, a papulovesicular acrodermatitis may be accompanied by severe pruritus. Parvovirus B19 DNA was also identified by polymerase chain reaction in a cutaneous biopsy specimen of a patient with papular-purpuric *gloves and socks* syndrome, an illness characterized by pruritic painful acral erythema associated with fever and mucosal lesions. Although proposed as an etiologic agent, parvovirus was not linked to Henoch-Schönlein purpura in children in one case control study.

The pathogenesis of the rash associated with B19 infection is not clear. However, since it usually coincides with measurable

Figure 1 Left side of this boy's face displaying slapped cheek appearance rash of erythema infectiosum, or *Fifth disease*

Figure 2 Hands of a school boy showing skin lesions of erythema infectiosum, or *Fifth disease*
Source: Public Health Image Library (PHIL), CDC, USA.

serum antibody production, it is presumed to be at least partially immune mediated. The role of serum antibodies in rash development is also suggested by the appearance of rash after IVIG administration to immunodeficient patients with chronic infection. Immune complexes have been detected during acute infection and are proposed to participate in the pathogenesis of the disease. B19 DNA and antigen have been detected in a skin biopsy specimen from a patient with EI, suggesting that direct infection of epidermal cells may also contribute to rash development. Approximately 75% of patients will develop a rash, although less than 20% will have the appearance of the typical malar (*slapped cheeks*) rash seen in EI.

Arthritis

Parvovirus B19 infection can present as an acute arthritis and may be mistaken for acute rheumatoid arthritis in the absence of rash. Arthralgia and/or arthritis are more common in adult females compared to adult males or children. Joint symptoms are usually symmetric and most frequently involve the small joints of the hands, wrists, knees, and feet. Joint symptoms usually resolve in three weeks, although a minority of patients may develop persistent

or recurring arthropathy. The arthritis associated with acute B19 infection does not cause joint destruction.

Hematologic Manifestations

Parvovirus B19 infection can lead to transient aplastic crisis and chronic anemia, depending on the host.

Transient Aplastic Crisis

Individuals with hematologic abnormalities, including increased RBC destruction (e.g., sickle cell disease, hereditary spherocytosis) or decreased RBC production (e.g., iron deficiency anemia) are at increased risk of developing transient aplastic crisis (TAC) secondary to parvovirus infection. Genotype 3 erythroviruses have also been associated with TAC. Patients with TAC usually present with pallor, weakness and lethargy secondary to severe anemia. Infection can rarely be fatal due to congestive heart failure, cerebrovascular accidents, and acute splenic sequestration. These patients usually do not have the characteristic rash. However, they often have an undetectable peripheral reticulocyte count and a drop in hemoglobin concentration of more than 30% secondary to complete arrest of erythropoiesis.

Chronic Anemia in Immunocompromised Hosts

Immunosuppressed patients are at risk of developing acute or chronic anemia following B19 infection due to lack of protective antibodies. Life-threatening anemia can develop due to the inability to mount an immune response to clear viremia. Chronic infection leads to chronic hypoplasia or aplasia of the erythroid series in the bone marrow, resulting in giant pronormoblasts and a reticulocytopenic anemia. Infection is usually not accompanied by rash or arthropathy, which may be due to the inadequate immune response in this patient population. Chronic infection and anemia have been described in leukemia, HIV, congenital immunodeficiency and recipients of organ transplants. Immunosuppressed patients respond well to intravenous immune globulin (IVIG); however, some patients require recurrent treatment for relapses. Resolution of parvovirus-induced anemia in HIV-infected patients after the initiation of highly active antiretroviral therapy has also been reported.

Parvovirus in Malaria-Endemic Areas

Severe anemia is a major cause of death among young children in developing countries and may be due to a variety of causes, including malaria, iron deficiency, and hookworm infections. Acute B19 infection is associated with an increase in the risk of severe anemia comparable to that associated with *Plasmodium falciparum*. The pathogenesis of anemia is due to direct destruction of erythrocyte progenitor cells, which dramatically reduces red cell production. During an acute infection, this results in a significant drop in hemoglobin. In healthy individuals, RBC production returns in 10–14 days with little anemia. However, in individuals with an increased RBC turnover, even a limited cessation of RBC production can lead to a clinically significant drop in hemoglobin and TAC. In patients unable to control B19 infection because of immunosuppression or immunodeficiency, lysis of RBC precursors leads to prolonged cessation of RBC production and the development of a severe, chronic pure red cell aplasia and anemia.

Nonimmune Hydrops Fetalis and Intrauterine Fetal Death

B19 infection during pregnancy can result in fetal complications including miscarriage, intrauterine fetal death and/or nonimmune hydrops fetalis. The fetus is especially susceptible to the effects of B19-induced anemia due to its shortened RBC half-life and the expanding RBC volume. The relatively immature fetal immune system is also less able to effectively control virus infection. The

ensuing fetal hydrops appears to result from the onset of severe anemia, which in turn causes high output heart failure. Fetal B19 infection can also present with thrombocytopenia.

Myocarditis

Parvovirus B19 infection has been associated with myocarditis, dilated cardiomyopathy, and isolated left ventricular diastolic dysfunction. Fatal myocarditis secondary to parvovirus B19 infection has also been described in a liver transplant recipient.

Renal Disorders

The possibility of a link between B19 infection and glomerular disease has been suggested from numerous case reports that describe onset of nephritis or nephrotic syndrome after onset of parvovirus infection. Several case reports have linked acute B19 infection to nephrotic syndrome in patients with sickle cell disease. Thrombotic microangiopathy, hemolytic uremic syndrome, and renal involvement in association with systemic vasculitides such as Henoch Schönlein purpura, polyarteritis nodosa and Wegener granulomatosis have also been associated with B19 infection. Case reports implicate parvovirus in the pathogenesis of proliferative glomerulonephritis and collapsing glomerulopathy, but a causal relationship has not been established. A proposed role for B19 infection is based on the temporal association of renal findings with viral infection, positive serology, and identification of the viral genome in the glomerulus. Patients who require dialysis may have increased susceptibility to acute and chronic anemia after parvoviral infection. Factors that predispose this population to complications of B19 infection include impaired immune response, deficient erythropoietin production, and possibly decreased erythrocyte survival. Chronic anemia and pure red blood cell aplasia are the most common complications of parvovirus infection in the postrenal transplant cases.

Other Disease Associations

B19 has been reported in association with a wide range of diseases, including arthritis, vasculitis, myocarditis, nephritis, lymphadenitis, idiopathic thrombocytopenic purpura, meningitis and encephalitis, hemophagocytic syndrome, and fulminant liver disease as well as many other conditions. Parvovirus B19 is also a recognized cause of isolated angioedema in neonates.

APPROACH TO DIAGNOSIS

The B19 immune status varies with acute infection, previous infection, and reactivation of infection.

Acute Infection

The choice of diagnostic testing for acute B19 infection will depend on the patient's immune status. In immunocompetent individuals, the preferred method is serologic testing to detect circulating B19-specific IgM and IgG antibodies. However, in the immunosuppressed patient, or for congenital infections, nucleic acid amplification testing (NAAT) is recommended. Detectable levels of B19-specific IgM can be found within 7–10 days of virus exposure and remain measurable for several months before diminishing. In some patients, B19-specific IgM antibodies can persist for six months or more. Therefore, the presence of these antibodies, especially at low titers, is suggestive but not conclusive proof of recent infection.

Acute infection can also be diagnosed by demonstrating a fourfold or greater rise in serum B19-specific IgG antibody titers. However, since this procedure requires two separate time points for sample collection, it is considered impractical in most clinical situations. Today, most serology testing will include concurrent analyses for both B19-specific IgM and IgG antibodies from a single blood sample. At present, NAAT is considered the most sensitive approach for direct detection of virus within a specimen,

and is the test of choice for diagnosing acute infection in the immunocompromised patients, including the fetus and neonate.

Previous Infection

Previous infection is best confirmed by serologic testing that detects B19-specific IgG antibodies. Documenting previous infection, which infers immunity, is a common practice in obstetrics when the physician is concerned about the immune status of a pregnant woman who has a history of exposure to an individual infected with B19, especially if the contact is her own school-aged or younger children.

Reactivation of Infection

Reactivation of persistent infection can occur in immunocompetent and, more often, immunocompromised individuals. These infections are confirmed by demonstrating the presence of the virus for a prolonged period. This is most often accomplished by NAAT to detect B19 DNA within a specimen. Individuals with persistent infection may also have measurable levels of B19-specific IgM antibodies over time if they are healthy enough to produce immunoglobulin. Unlike NAAT, serology testing does not appear to differentiate between the genotypes, as the level of divergence among the strains at the amino acid level is significantly less than that seen at the nucleotide level. Appropriate clinical specimens for NAAT analysis include serum, plasma, bone marrow, amniotic fluid, and placental and fetal tissues. As with any diagnostic test, NAAT can produce false positive and/or false negative results.

Antigen Detection

Immunohistochemical (IHC) techniques can be used to detect B19 antigens in a variety of tissues, especially fetal and placental tissues.

Virus Isolation

Freshly harvested bone marrow or fetal cord blood, or several continuous cell lines can support low level B19 replication in vitro. However, these in vitro systems have not been used for clinical applications.

MANAGEMENT (TABLE 3)

Treatment of Acute Infection

Treatment of symptomatic B19 infection varies with the clinical manifestation. Erythema infectiosum (*fifth disease*) is a self-limited, mild illness most often occurring in children. There is no specific therapy and usually no indication for symptomatic treatment. In some patients, symptomatic therapy for arthralgia, arthritis, or pruritus may be indicated. Nonsteroidal anti-inflammatory drugs can provide symptomatic relief. There is limited data to support the use of IVIG treatment for B19-associated arthropathy. The anemia in TAC is often severe enough (hemoglobin levels below 6 g/dL with few or no reticulocytes) to require transfusion until the patient's immune response eliminates the infection and red cell production returns. The usual course of parvovirus associated anemia is spontaneous resolution within a few days to weeks.

Treatment of Chronic Infection with Anemia

Most patients with chronic B19 infection and anemia have received immunosuppressive therapy for cancer, leukemia, or tissue transplantation, have a congenital immunodeficiency or have HIV-associated immunodeficiency. Most of these reports have occurred prior to the availability of potent antiretroviral therapy (ART). Even in the absence of immunodeficiency pure red cell aplasia has been described. The anemia usually responds to IVIG treatment with a reticulocytosis within one week, and the chronic viremia was cured after periodic IVIG infusions over four months. In such cases it may be warranted to look for in vitro abnormalities in T- and B-cell function.

Table 3 Treatment options for symptomatic parvovirus B19 infection

Manifestation	Treatment options
Erythema infectiosum	None or symptomatic
Arthritis or arthralgia	NSAIDs
Transient aplastic crisis	Transfusion and oxygen if needed
Fetal hydrops	Intrauterine blood transfusion (?)
Chronic infection with anemia	IVIG and transfusions
Chronic infection without anemia	IVIG (?)

Abbreviation: IVIG, intravenous immunoglobulin.

Patients have been treated with several different IVIG regimens, such as 400 mg/kg of commercial IVIG for 5 or 10 days or 1000 mg/kg for 3 days, both with good results. Relapses in these patients have been successfully treated with maintenance IVIG at doses of 0.4 g/kg/day every four weeks.

Treating Chronic Infection without Anemia

Chronic B19 infection has been demonstrated in patients without anemia or underlying immunodeficiency. It is not clear if IVIG treatment is helpful in this setting.

PREVENTION

The best measures currently available to prevent B19 infection are those designed to interrupt transmission by good infection control practices. A recombinant human parvovirus B19 vaccine, composed of the VP1 and VP2 capsid proteins was evaluated in a randomized, double-blind, phase 1 trial. In 2007, a phase I/II trial was undertaken to assess the safety and immunogenicity of a recombinant B19-parvovirus vaccine. However, this study has been suspended due to vaccine-associated adverse events.

IN A NUTSHELL

1. Parvovirus B19 replicates in erythroid progenitor cells of the bone marrow and blood leading to inhibition of erythropoiesis.
2. Viremia occurs one week after exposure and usually lasts approximately 5 days, with virus titers peaking on the first few days of infection. Development of a robust antibody response corresponds to viral clearance and subsequent protection from disease.
3. There are five well-established syndromes associated with B19 infection: (1) Fifth disease (erythema infectiosum), (2) Arthropathy; (3) Nonimmune hydrops fetalis, intrauterine fetal death, or miscarriage; (4) Transient aplastic crisis in those with chronic hemolytic disorders; and (5) Chronic pure red blood cell aplasia (B19-PRCA) in immunocompromised individuals.
4. In children, EI begins with nonspecific prodromal symptoms, followed by a classic erythematous malar rash and lacy appearance on the extremities.
5. B19 infection during pregnancy can result in fetal complications including miscarriage, intrauterine fetal death and/or nonimmune hydrops fetalis.
6. There is no specific antiviral drug currently available for treating patients infected with B19. Likewise, no vaccine exists for preventing the infection.
7. In most instances, treatment is directed toward symptoms but in some instances antiviral treatment with IVIG is indicated. Until a vaccine is developed and becomes available, good hygienic practices should be the focus of prevention strategies.

Chapter 31.8

Roseola Infections

Swati Singhal

Human herpes virus 6 (HHV 6) and Human herpes virus 7 (HHV 7) are human pathogens of emerging clinical significance. HHV 6 was first isolated from patients with lymphoproliferative disorders in 1986. It was established to be a causative agent of roseola infections in 1988. HHV 7 is known since 1990 and bears many similarities with HHV 6. It is postulated that most clinical infections by HHV 6 are caused by the HHV 6 B variant. Roseola infantum, also known as *exanthem subitum*, refers to the prototype exanthematous illness caused by HHV 6. HHV 6 infections are ubiquitous in children less than 2 years of age.

EPIDEMIOLOGY

Infections by HHV 6 are known to occur across all geographical regions with no seasonal variations and no known outbreaks. For reasons that are not yet clear, it is reported more frequently from Japan. There is no local Indian data available but it is felt to be a common childhood exanthematous illness. Neonates and infants younger than 6 months have transplacentally acquired antibodies and are immune to infection. Subsequently, passive immunity starts to fade and the child gets prone to develop infection. The most common age group to get affected is from 6 months to 15 months of age. The immunity after primary infection is usually lifelong. Immunological studies indicate that almost 90% adults are seropositive for infection. It is possible for infection to get reactivated in immunocompromised states.

ETIOLOGY

Not all HHV 6 infections are roseola and not all roseola infections are caused by HHV 6. Roseola infections are commonly caused by HHV 6 and less commonly by HHV 7. A minority of roseola infections are caused by Echovirus 16. It is noteworthy that roseola is the most prototypical but not the most common clinical manifestation of HHV 6. The most common manifestation of HHV 6 in immunocompetent infants is a nonspecific febrile illness.

PATHOGENESIS

HHV 6 is distinguished into two forms as HHV 6 A and HHV 6 B based on distinct genetic, immunological and biological features. HHV 6 B variant accounts for the majority of clinical disease conditions. The exact role of HHV 6 A in disease states is unclear but it is postulated that it might cause severe illness in immunocompromised individuals. HHV 7 is closely linked to HHV 6 B and its pathogenetic mechanism is very similar to HHV 6 B. The exact mode of transmission for these viruses is unclear. It is postulated that they are shed in the saliva of healthy adults. The infection is possibly acquired through oral/nasal or conjunctival mucosa. The virus eventually establishes itself mainly in circulating CD4 T lymphocytes, but also in macrophages, dendritic cells, fibroblast, epithelial cells and bone marrow progenitors. It has been demonstrated that congenital transmission of HHV 6 takes place in approximately 1% of newborns, but the clinical significance of this is yet to be established. The exact mechanisms of the characteristic rash of roseola infantum are not known.

CLINICAL FEATURES

Infections in Immunocompetent Individuals

This group accounts for the vast majority of children affected with HHV 6 and HHV 7. The infection can be described in two stages. The *prodromal stage* consists of nonspecific and variable presence of malaise and other viral prodromes like rhinorrhea and pharyngeal injection. This is followed by the *febrile stage* which typically consists of high grade fever, but the child is otherwise well. There could be mild edema of eyelids and posterior cervical lymphadenopathy. Infants in Asian countries might develop ulcers at the uvulopalatal junction, known as Nagayama spots. Up to 5–10% children might experience febrile seizures in this stage. The fever usually lasts for 2–3 days and often ceases abruptly (crisis), sometimes to subnormal levels. Occasionally, the fever might take time to subside (lysis). In most cases, the disease process is limited to this stage. There are usually no further complications and the episode might be clinically diagnosed as a nonspecific febrile illness. *In 30% children, the febrile phase is followed by the onset of a sudden rash.* The rash is a discrete maculopapular rash, starting from the trunk and spreading to rest of the body. The rash is nonitchy and there are typically none to minimal systemic features. The rash subsides in another 2–4 days' time. It is this clinical presentation of a febrile stage followed by a characteristic rash which is known as Roseola Infantum or Exanthem Subitum (*Subitum* refers to *rapid* in Latin language).

In a large prospective study involving emergency hospital visits for febrile children less than 3 years of age, primary HHV 6 infection accounted for 10% of overall cases and 21% cases in the age group of 6–12 months. Thirteen percent of these children had febrile seizures and these accounted for 33% of all children with febrile seizures less than 2 years of age. *Febrile seizures are the most common central nervous system manifestation of primary HHV 6 infection.* The exact mechanism of this is not known but could be a result of direct invasion by the virus. Rarely, the manifestations could be more severe and result in bulging fontanel, meningoencephalitis or encephalopathy.

Usually, the illness runs a benign course, but there have been occasional case reports of infants developing thrombocytopenia, granulocytopenia, fulminant hepatitis and disseminated infection. Primary infection after the age of 2 years is rare. It most commonly presents as infectious mononucleosis like illness or an undifferentiated febrile illness. HHV 6 B has been implicated in the pathogenesis of many other medical disorders like multiple sclerosis, chronic fatigue syndrome, Hodgkin and non-Hodgkin lymphomas, leukemia and myocardial dysfunction, but the exact causative role is yet to be established. It is also postulated that HHV 6 infection might be contributing to the development of severe drug hypersensitivity syndrome. The direct consequences of HHV 6 A infection are not known.

The illness caused by HHV 7 is clinically indistinguishable from HHV 6 illness. Epidemiologically, HHV 7 might affect slightly older children (median age 22 months with HHV 7 and 9 months with HHV 6) and the duration of fever might be shorter with slightly lower mean temperatures.

Infections in Immunocompromised Individuals

Since HHV 6 and HHV 7 establish latent infection in leukocytes, they play important role in disease causation in immunocompromised hosts. There has been extensive evidence to suggest that HHV 6 infections can lead to serious disease in children with HIV, organ transplant and stem cell transplant recipients. The illness could range from an undifferentiated febrile illness to more serious and localized infections like encephalitis, bone marrow suppression and interstitial pneumonitis. Fatalities have been reported due to these

complications. The disease process in such patients most likely represents reactivation of a previously acquired infection. Most infections are caused by HHV 6 B, but recent case reports suggest that HHV 6 A might also cause giant cell hepatitis and fatal disease. HHV 6 and HHV 7 have been shown to have immunomodulatory properties and might have an indirect effect on viral infections (especially CMV), fungal infections and allograft rejection.

DIAGNOSIS

It is vital to establish the *sequence of symptoms* when evaluating a child with a febrile exanthematous illness. *The distinct history of 3 days of sustained fever in a child 6–15 months age, followed by appearance of a maculopapular eruption after subsidence of fever, is very characteristic of roseola infections.* If the infant is seen during the febrile stage of the illness, it might be difficult to distinguish it from other viral and bacterial illnesses. One noteworthy feature is the nontoxic appearance of the infant, despite the high grade fever. The occurrence of a seizure at this stage might mimic meningoencephalitic illness and might warrant close supervision and appropriate management. This might include admitting the child and further investigations.

If the infant is seen during the exanthematous stage, the presence/absence of other systemic features is crucial. The absence of fever at this stage is likely to be a result of HSV 6/HSV 7 infection. In infants who receive antibiotic treatment during the high grade febrile phase of illness, and subsequently develop a rash, it might be difficult to ascertain if the rash is due to roseola or due to drug eruption. Drug rashes are usually morbilliform and pruritic and resolve well after discontinuing the antibiotic. However, if the infant is still febrile when the rash is present, and has associated features, it is unlikely to be due to roseola. In the Indian context, it is crucial to be able to distinguish more serious illnesses like measles and rubella. Measles is characterized by the appearance of the rash at the *height of the febrile phase and the presence of associated features* like conjunctivitis, cough and rhinorrhea in a *sick looking child*. Another viral illness that needs to be differentiated is rubella. Rubella is characterized by *low grade fever* and the presence of *distinct prodromal features*. The rash in rubella also tends to be more extensive and confluent than that of roseola. In most cases, *a sound clinical judgment based on history and a thorough clinical examination is all that is required to establish the diagnosis of roseola infections.* The diagnosis can be confirmed by serodiagnosis and isolation of the virus by viral culture, antigen assays, and polymerase chain reaction (PCR). Seroconversion is often used to establish the diagnosis in primary infections. Other investigations are difficult and hence might be difficult to carry out in a resource constrained setting.

Blood investigations might reveal leukopenia and relative lymphocytosis, which might help differentiate from other serious bacterial illnesses. The cerebrospinal fluid (CSF) analysis in infants presenting with febrile seizure is usually normal. In the event of encephalitis or meningoencephalitis, the CSF might show mild pleocytosis and slightly high protein levels.

MANAGEMENT

The generally benign and self limiting nature of HHV 6 and HHV 7 infections in immunocompetent infants implies that supportive treatment is all that is required with no role of routine antiviral therapy. Fever can be managed by tepid water dressings and antipyretics. The infant might need supplemental feeds to prevent dehydration. Reassurance to caregivers is of utmost importance. They should be informed regarding the disease process and no necessity for antibiotics or antiviral drugs. Also,

they need to be updated that most of the older children and adults are immune to infection. A follow-up visit should be arranged within the next 48 hours to ensure due recovery of the infant.

The treating physician needs to be aware of the risk of serious disease in immunocompromised children. No standard antiviral treatment regimens are available, but most studies report using ganciclovir, foscarnet and cidofovir (either alone or in combination) for treatment of severe complications in this susceptible group. However, there is no role of routine chemoprophylaxis to prevent HHV related disease.

PROGNOSIS

Most infants do extremely well after recovering from the febrile and/or the rash phase. There are no long-term sequelae in immunocompetent children. Immunocompromised children might have severe and occasional fatal disease outcomes.

PREVENTION

Currently, there are no guidelines so as to prevent HHV 6 and HHV 7 transmission as HHV 6 infection is considered to be ubiquitous in children less than 2 years of age. There is no role of prophylaxis even in high risk patients.

IN A NUTSHELL

1. HHV 6 and HHV 7 usually cause benign viral illness.
2. It usually affects children less than 2 years of age and has a distinct pattern of high grade fever followed by rash on resolution of the fever.
3. It is important to be able to clinically distinguish it from other serious viral and bacterial illnesses.
4. Treatment is mainly supportive in immunocompetent individuals.
5. The treating physician needs to be aware of disease complications in high risk groups.

Chapter 31.9

Viral Hepatitis

Amit Goel, Chhavi Nanda

Hepatitis means inflammation of the liver irrespective of its cause, severity or duration. It is often associated with yellow discoloration of eyes and urine and elevated serum levels of liver enzymes, i.e., alanine aminotransferase (ALT) and aspartate aminotransferase (AST), though a subset can be asymptomatic. The most common cause is infection with one of the hepatotropic viruses; other causes are nonhepatotropic viruses (cytomegalovirus, herpes-simplex, varicella-zoster, dengue virus), bacterial agent (*Salmonella typhi*), parasites (*Plasmodium* species), drugs (antitubercular, anti-epileptic, halothane), ischemia (ischemic hepatitis), autoimmune conditions (autoimmune hepatitis), etc. The five known hepatotropic viruses [called hepatitis A virus (HAV), hepatitis B virus (HBV), hepatitis C virus (HCV), hepatitis D virus (HDV), and hepatitis E virus (HEV), respectively] affect primarily the liver, and thus present mainly with liver disease; the term *viral hepatitis* is usually reserved for infection with these viruses.

The infection and liver injury can be either short lasted (*acute*) or prolonged (chronic, empirically defined as > 6 months). HAV and HEV cause only acute viral hepatitis (AVH). In contrast, infection with HBV, HCV or HDV may lead to chronic or persistent infection, resulting in chronic viral hepatitis.

EPIDEMIOLOGY

Viral hepatitis occurs in all parts of the world, though its burden is higher in resource-poor countries in Asia and Africa, primarily because of high population density, poor water quality and sanitation, financial constraints, and lack of education and awareness. In India, HAV and HEV infection are very common. Nearly 1–3% of Indian population has chronic HBV infection and nearly 0.5–1.5% has chronic HCV infection. About 10–20% of chronic HBV infected individuals carries simultaneous HDV infection. In India, jaundice accounts for 1.5–2.2% of all hospitalizations.

ETIOLOGY

Hepatotropic viruses A to E differ markedly in their structure, epidemiology, host predilection, routes of transmission, incubation period, clinical presentations, natural history, diagnosis, and preventive and treatment options (**Table 1**).

Hepatitis A virus accounts for over 60% of cases with acute viral hepatitis or acute liver failure in Indian children. Over 90% of children have evidence of HAV infection by adolescence. Majority of HAV-infected children below 2 years are asymptomatic whereas children above 5 years are symptomatic. It is noteworthy that HAV related AVH in adults is more severe and carries rather higher risk for acute liver failure (ALF).

Hepatitis B virus causes acute as well as chronic infection and is the most common hepatotropic viral cause for liver cirrhosis and hepatocellular carcinoma in Asia, including India. Following HAV, HBV is the second most common hepatotropic virus causing AVH in children in India.

Table 1 Salient features of various hepatotropic viruses and associated disease

Feature	Virus				
	HAV	HBV	HCV	HDV	HEV
Virus size (nanometer)	28	42	50	35–37	32–34
Nucleic acid	RNA	DNA	RNA	RNA	RNA
Disease frequency in children and epidemiology	Most common cause of AVH in childhood	Second most common cause of AVH in childhood	Uncommon	Uncommon in India	Infrequently cause for AVH in children
Usual routes of transmission	Fecal-oral	Parenteral, mother-to-infant, sexual	Parenteral, mother-to-infant, sexual	Parenteral, sexual	Fecal-oral
Incubation period (d)	14–28	45–180 (usually 60–90)	15–150	30–180	15–60
Clinical syndromes	Acute viral hepatitis Acute liver failure (infrequent)	Acute viral hepatitis Chronic hepatitis Acute liver failure (infrequent)	Chronic hepatitis (very uncommon in children) Acute viral hepatitis (extremely infrequent)	HBV-HDV co-infection HDV super-infection in persons with chronic HBV infection	Acute viral hepatitis Acute liver failure (infrequent) Chronic hepatitis (very rare; not reported from India)
Chronicity and complications	No	Yes; may lead to cirrhosis and liver cancer	Yes; may lead to cirrhosis and liver cancer	Yes, with chronic HBV infection	Rare, in transplant recipients and immunosuppressed persons
Diagnostic test(s)	IgM anti-HAV Antibody	HBsAg (acute/chronic) IgM anti-HBc antibody (acute infection)	Anti-HCV and HCV RNA	IgM anti-HDV antibody, HDV RNA	IgM anti-HEV antibody
Treatment	None	Oral nucleoside analogs, or interferons	Combination of pegylated interferon and ribavirin; newer directly-acting anti-viral agents	Pegylated interferon	None for acute hepatitis Ribavirin for chronic infection
Vaccine	Yes	Yes	None	Yes (HBV vaccine)	Developed; not yet commercially available in most of the world

Abbreviations: HAV, hepatitis A virus; HBV, hepatitis B virus; HCV, hepatitis C virus; HDV, hepatitis D virus; HEV, hepatitis E virus; RNA, ribonucleic acid; DNA, deoxyribonucleic acid; AVH, acute viral hepatitis.

Hepatitis C virus related AVH is extremely rare. HDV infection can occur only in the presence of HBV infection, either simultaneously with acquisition of HBV (HBV-HDV coinfection) or as a piggy-back infection in persons with pre-existing chronic HBV hepatitis (HDV superinfection).

Hepatitis E virus is uncommon in children but is the most common cause of AVH and ALF in adults in India. Acute hepatitis E is uncommon in children particularly before adolescent age. This is possibly because HEV infection in children is most often asymptomatic.

PATHOGENESIS

Hepatitis A virus and HEV enter the body by oral route through fecal contamination of food and water, multiply in hepatocytes, followed by excretion in stool for a variable period of time. Person to person transmission is common with HAV but not with HEV. They have no cytopathic effect on hepatocyte, i.e., they do not destroy infected hepatocyte. Hepatocyte damage is the result of bystander injury during the natural immunity attempting to clear virus. Infiltrating lymphocyte in an attempt to clear virus from body, kills infected hepatocyte which result in various clinical and biochemical manifestations of liver injury such as serum transaminase elevation, jaundice, coagulopathy, liver failure, etc. Acute hepatitis is characterized by widespread hepatocyte necrosis followed by regeneration without leaving any stigma of previous disease.

Hepatitis B virus, takes advantage of being a DNA virus, enters into hepatocyte nucleus and integrates with host DNA thus forming covalently closed circular DNA (cccDNA), which remains inside the body for rest of the host's life. This causes chronic HBV infection.

About 70% of HCV infection leads to chronic infection. Several mechanisms are proposed which helps HCV to deceive the natural immunity and establish chronic infection in majority. Few of those mechanisms include high degree of genetic variability thus forming HCV quasi-species, mutations leading to altered innate immune cell functions, genetic susceptibility to HCV infection, impaired adaptive immune response, impaired antigen presenting cell function and failure to generate HCV specific T-cells.

On histopathology, chronic viral hepatitis, irrespective of viral cause, is characterized by infiltration with inflammatory cells (predominantly lymphocytes), ongoing necro-inflammation, variable amount of liver fibrosis and development of regenerating nodules, which together lead to progression to cirrhosis.

CLINICAL FEATURES

Hepatotropic virus infection may take three possible courses which, in order of frequency, are AVH, chronic viral hepatitis, and ALF. Acute viral hepatitis is a syndrome common to infection with all hepatotropic viruses. It typically runs a tri-phasic course: prodromal, icteric, and convalescent phases. All the patients may not evolve into icteric phase. Different phases are discussed here briefly, and more details are included in **Table 2**.

Prodromal phase Anorexia is the hallmark of prodromal phase, particularly in children. This phase lasts for a few days, but may occasionally extend to 3 weeks. Serum alanine aminotransferase/aspartate aminotransferase (ALT/AST) levels are the maximum at this phase. However, the degree of ALT/AST elevation has no relation with disease severity or outcome. Occasional child may worsen to ALF. Every hepatitic prodrome is not necessarily followed by icteric phase, particularly with HAV infection.

Icteric phase It follows viral prodrome and is heralded by yellow discoloration of eyes and urine. Onset of jaundice is often associated with improvement of the prodromal symptoms and appetite. The jaundice lasts for a variable period of a few weeks.

Convalescent phase Most of the children with AVH achieve complete clinical and biochemical recovery during this phase. This is the rule with HAV and HEV infection.

A minority of children with HBV infection and a majority of those with HCV infection progress to chronic hepatitis. Chronic viral hepatitis is a result of prolonged, ongoing, slow inflammatory injury to hepatocytes accompanied by regeneration and fibrosis. It may ultimately, though in a small proportion, culminate into liver cirrhosis which is characterized by ascites, variceal bleeding, hepatic encephalopathy, hepatorenal syndrome and occasionally hepatocellular carcinoma. Acute liver failure, which is a result of sudden massive loss of hepatocyte function, is characterized by coagulopathy and altered sensorium and will be dealt elsewhere separately.

Atypical Features of Acute Hepatitis A

Cholestatic Hepatitis

This clinical form, though relatively uncommon, is seen in children recovering from acute HAV. The patients continue to have deep icterus during the convalescent phase. This is accompanied by intense pruritus, which may impair sleep, work, and quality of life.

Table 2 Salient features of three phases of viral hepatitis

Symptoms	Signs	Laboratory
Prodromal phase		
<ul style="list-style-type: none"> • Precedes jaundice • Anorexia, aversion of taste and smell (80–90%) • Nausea, vomiting • Abdominal discomfort, right upper quadrant pain • Low grade fever • Malaise, myalgia, fatigue, arthralgia • Headache, photophobia, neck rigidity (occasional) • Lasts for 5–7 days 	<ul style="list-style-type: none"> • No icterus • Mild, soft hepatomegaly • Right upper quadrant mild tenderness • Serum sickness-like features: arthritis, skin rash (particularly acute hepatitis B) • Occasional mild, soft, non-tender splenomegaly 	<ul style="list-style-type: none"> • Normal bilirubin • Marked elevation of ALT and AST (usually >10-fold, up to 100 times, peak in prodromal or early icteric phase) • Slight elevation of alkaline phosphatase • Normal or mildly deranged prothrombin time in absence of acute liver failure
Icteric phase		
<ul style="list-style-type: none"> • Yellow discoloration of eyes and urine • Improvement of appetite and other prodromal symptoms • Feeling well and active • In some, mild itching • Lasts for up to 6 weeks 	<ul style="list-style-type: none"> • Jaundice of variable severity • Mild, soft hepatomegaly • Occasional mild, soft, non-tender splenomegaly • Scratch marks, if itching present 	<ul style="list-style-type: none"> • High serum bilirubin, predominantly conjugated • Moderately elevated ALT and AST
Convalescent phase		
<ul style="list-style-type: none"> • Almost complete recovery of symptoms • Mild icterus and fatigue may persist for a few weeks 	<ul style="list-style-type: none"> • Icterus—moderate to mild; gradually improving • Normalization of urine color • Regression of organomegaly 	<ul style="list-style-type: none"> • Near normal bilirubin • Normal or slightly elevated ALT and AST • Normal alkaline phosphatase

These symptoms may continue for a few weeks to months, with spontaneous and complete recovery. Patients need counseling and antipruritic measures while awaiting natural recovery.

Relapsing Hepatitis

Up to 10% of children with hepatitis A may have a biphasic illness, which probably represents endogenous reinfection due to prolonged enterohepatic circulation of HAV. It is characterized by second attack of hepatitis 4–8 weeks following the initial recovery. The second attack is usually in the form of either subclinical elevation of transaminases or mildly symptomatic disease; however, sometimes, a full blown attack of hepatitis may occur. Rarely, multiple relapses, with each episode associated with viral excretion in stool, may occur. Relapsing hepatitis finally recovers fully.

Progression to Autoimmune Hepatitis

Rarely, patients recovering from HAV infections have been shown to develop autoimmune hepatitis. Its occurrence possibly depends on individual susceptibility for autoimmune hepatitis, which is merely precipitated by HAV infection.

Extrahepatic Manifestations

Occasionally, HAV infection may be associated with involvement of other body organ systems, such as kidney (proteinuria, glomerulonephritis, nephrotic syndrome, acute renal failure), nervous system (aseptic meningitis, encephalitis, seizure, myelitis, Guillain-Barré syndrome, mononeuritis, mononeuritis multiplex), pancreatobiliary organs (acalculous cholecystitis, acute pancreatitis), and hematological system (autoimmune hemolytic anemia, pure red cell aplasia, aplastic anemia). These manifestations have also been reported in persons with infection due to other hepatotropic viruses, though with a somewhat lower frequency.

DIFFERENTIAL DIAGNOSIS

Diagnosis in a child presenting with fever, systemic symptoms, and jaundice in summer or rainy season may at times be confused with other water-borne or vector-borne infections with similar presentation. Occasionally, in a child, AVH needs to be

distinguished from acute exacerbation of a pre-existing chronic liver disease. In a child with suspected AVH, an alternative diagnosis should be considered, if the child (1) does not show expected recovery; (2) worsens in the absence of features indicating acute liver failure; (3) continues to have fever after appearance of jaundice; or, (4) has atypical clinical features. **Table 3** summarizes the clinical and laboratory features that help to differentiate AVH from other diseases.

Approach to Diagnosis

Diagnostic algorithm for approaching a child with suspected AVH is summarized in **Flow chart 1**. In every child with AVH, one should be on the lookout for clinical and biochemical features of ALF, which needs special care and management.

MANAGEMENT

Acute viral hepatitis needs no specific therapy; rather only supportive measures and careful monitoring are needed.

Supportive Therapy

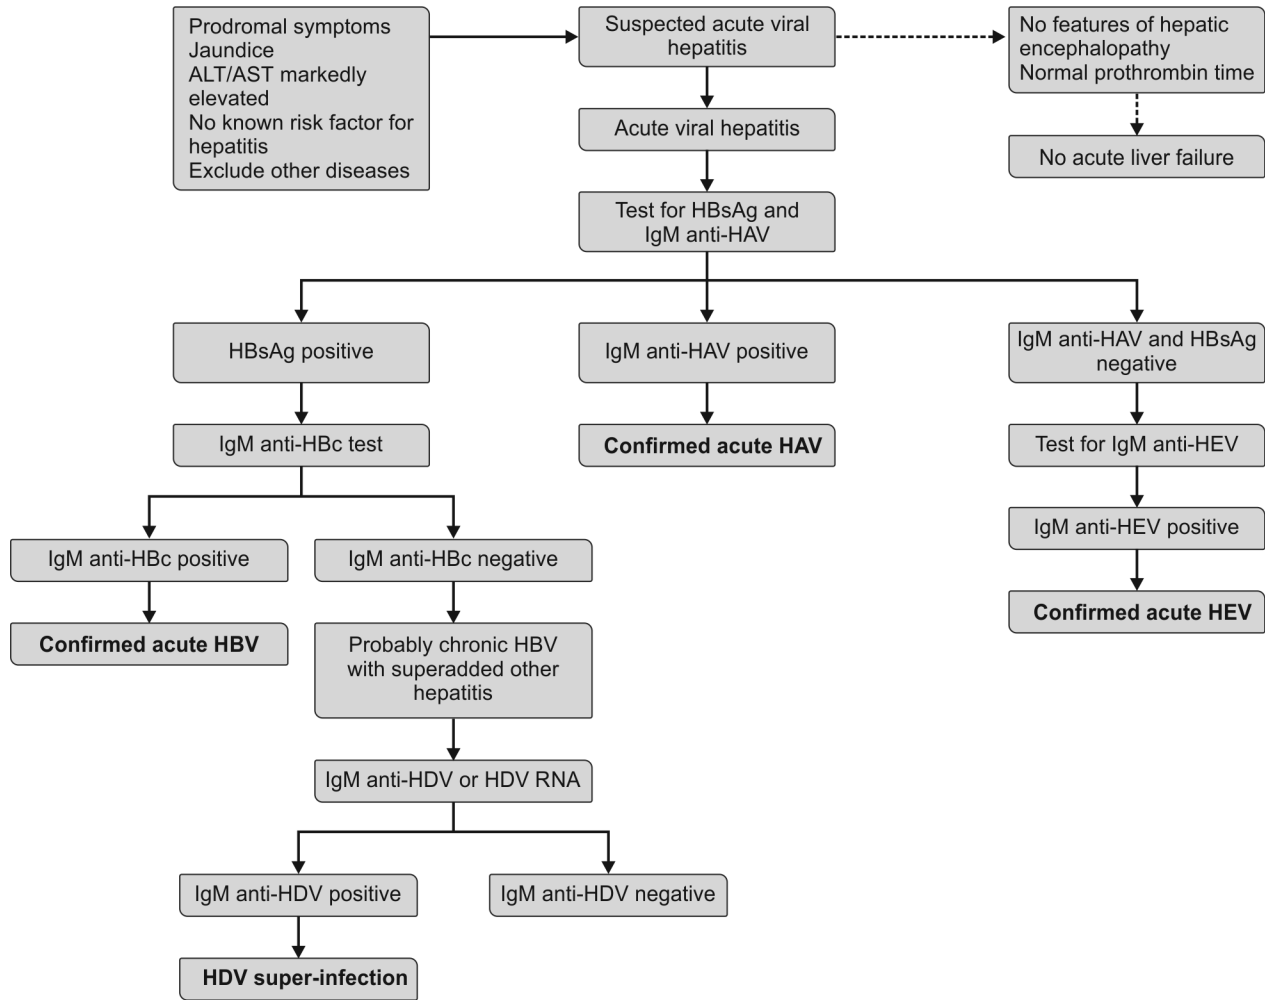

Child can continue his daily routine with light physical activity till symptoms subside. There is no role for strict bed rest. Hygienic measures help prevent spread to other family members. Use of boiled water after the onset of AVH is of no use. Antipyretic, antiemetic and mild analgesic drugs may be used for symptomatic relief. Vitamins (particularly vitamin K), appetizers, antibiotics, hepatoprotective medications (e.g., Liv-52, ursodeoxycholic acid), etc. have no role. Dietary restrictions (of fat, milk, turmeric, pickles, spices, etc.) offer no benefit and may in fact adversely impact nutrition.

Counseling

Parents should be counseled about (1) benign nature of illness, (2) high likelihood of complete natural recovery, (3) avoidance of restrictions on physical activity and diet, and (4) lack of role for drugs including antiviral agents. For hepatitis B and C, need to follow-up till viral clearance should be emphasized, in view of possibility of chronicity.

Table 3 Differential diagnosis of acute viral hepatitis

Differential diagnosis	Symptoms	Signs	Investigations
Malaria	Moderate to high grade intermittent fever with chills and rigor	Pallor; moderate splenomegaly	Anemia; mild unconjugated hyperbilirubinemia; reticulocytosis; intravascular hemolysis; malaria parasite positive; relatively moderate ALT/AST elevation
Dengue hepatitis	Severe body ache	Petechial rash	Thrombocytopenia; dengue antibody or antigen (NS1) test positive; mild to moderately elevated bilirubin, ALT, AST; ascites or pleural effusion
Enteric hepatitis	Continuous high-grade fever	Toxic look; poor general condition; moderate splenomegaly	Leukopenia; blood culture or Widal test positive
Acute exacerbation of chronic liver disease	History of factors predisposing to chronic liver disease; symptoms of chronic liver disease (ascites, gastrointestinal bleed, encephalopathy)	Ascites; firm splenomegaly; dilated abdominal veins; encephalopathy; stigmata of chronic liver disease	Pancytopenia; low albumin; prolonged prothrombin time; ultrasound features of cirrhosis; gastroesophageal varices on endoscopy
Liver abscess	Marked right upper quadrant pain; breathing difficulty	Right upper quadrant or right intercostal tenderness; tender hepatomegaly; right-sided pleural effusion	Leukocytosis; mildly elevated bilirubin, no or mild ALT/AST elevation; ultrasound abdomen showing liver abscess
Cholangitis	Moderate to high grade intermittent fever with chills; biliary pain	Firm, moderate hepatomegaly; features of biliary disease, e.g., palpable gallbladder	Marked conjugated hyperbilirubinemia; mildly elevated ALT, AST; marked elevation of alkaline phosphatase and γ -glutamyl transferase; ultrasound abdomen showing biliary radicle dilatation

Flow chart 1 Algorithm to approach a child with suspected viral hepatitis

Monitoring

A child with AVH needs to be monitored for possible complications particularly ALF. Child could be monitored for age appropriate subtle signs of hepatic encephalopathy such as flapping tremors, altered sleep patterns, excessive irritability and inconsolable cry. The only laboratory test we need to monitor is prothrombin time, if it was abnormal earlier or there is any clinical evidence of deterioration. Prolongation of prothrombin time is the most reliable and early marker of worsening liver function or impending liver failure. Repeated measurement of no other liver function tests, including bilirubin and serum transaminases levels, are needed to monitor a child with acute hepatitis.

PROGNOSIS

Barring occasional cases that develop ALF, most children with AVH have spontaneous and complete recovery without any sequelae. Children with ALF have high risk of mortality in lack of intensive care setting and liver transplantation facility. Akin to AVH, children survived of ALF will not be left with any sequelae or persistent liver damage. As discussed earlier, some children with acute HBV and majority of those with HCV infection will develop chronic hepatitis. Risk of developing chronic HBV is primarily determined by the age of infection acquisition, with risk being much higher when the infection occurs in infancy (> 90%) or early childhood (> 20% if age < 5 years) and below 5% when it occurs in adulthood. Over the decades, a small proportion of chronic infection with HBV or HCV

may culminate in liver cirrhosis. Liver cirrhosis is associated with impaired quality of life, life threatening morbidities and high risk of death.

PREVENTION

Viral hepatitis could be prevented by changing our different practices, vaccination or immunoglobulin administration (**Table 4**). Effective vaccines are available against HAV and HBV. HDV infection can be prevented by preventing HBV infection. Vaccines and immunoglobulin will be dealt elsewhere in details.

IN A NUTSHELL

1. Five hepatotropic viruses, A to E, cause majority of acute viral hepatitis episodes.
2. Hepatitis A virus followed by hepatitis B virus are the most common viral agent for hepatitis in children in India.
3. Clinical course of acute viral hepatitis due to various hepatotropic viruses is indistinguishable.
4. Most patients with viral hepatitis improve spontaneously.
5. In patients with acute viral hepatitis, degree of ALT/AST elevation has no relation with disease severity or outcome.
6. Only a few children with acute viral hepatitis progress to liver failure.
7. HBV or HCV infection may progress to chronic hepatitis.

Table 4 Summary of preventive measures applicable for children against hepatitis viruses, A to E

<i>Preventive measures</i>	<i>HAV</i>	<i>HBV</i>	<i>HCV</i>	<i>HDV</i>	<i>HEV</i>
Water and food hygiene, and sanitation measures	Yes				Yes
Safe injection practices		Yes	Yes	Yes	
Safe blood/blood product transfusion		Yes	Yes	Yes	
Antenatal screening		Yes			
Vaccination	Yes	Yes		Yes, hepatitis B vaccine	
Immunoglobulin	Yes	Yes			

Abbreviations: HAV, hepatitis A virus; HBV, hepatitis B virus; HCV, hepatitis C virus; HDV, hepatitis D virus; HEV, hepatitis E virus

Chapter 31.10

Rabies

Jaydeep Choudhury

Rabies is acute viral encephalitis transmitted by exposure to rabid animals. It is principally a zoonotic disease. It is considered as one of the most dreaded diseases. The term *exposure* to rabies means bite, scratch or lick directly on mucous membrane or on broken skin and also aerosol infection by infected animals. Organ transplant can also transmit this disease. When infection sets in, rabies is invariably fatal. On the other hand rabies is a vaccine preventable disease, especially when vaccination is combined with immunoglobulin therapy.

EPIDEMIOLOGY

Rabies is endemic in many of Asian and African countries. India is a high endemic country for rabies. Only the islands of Andaman and Nicobar in east and Lakshadweep islands are rabies free. According to latest WHO estimates, about 50,000 human deaths due to rabies are reported every year in the world. It is estimated that about 20,000 human rabies deaths occur in India every year. The annual animal bite incidence is 17.4 per 1000 population. The biting animal mainly responsible for human rabies death was dog. It is estimated that 96.3% of all reservoirs of rabies are dogs. Majority were stray dogs (75.3%) followed by pets (11.1%), wild (3.5%) and otherwise or unknown (10.2%).

VIRUS

Rabies virus is a single stranded RNA virus belonging to the genus *Lyssavirus* of the family *Rhabdoviridae*. The rabies virus is a typical bullet shaped virus measuring usually 100–300 nm in length depending on strain and 75 nm in breadth. Rabies virus is a neurotropic virus. It has phospholipid envelop which has glycoprotein spikes on surface. The surface projection of glycoprotein, which is related in attachment of virus to susceptible cells, also carries the antigen which elicits the production of neutralizing antibody when isolated in animals and hence affords protection against the disease. The rabies virus is resistant to cold temperature, dryness and decays but is rapidly inactivated by the action of oxidizing agents, solvents, quaternary ammonium compounds, soap and detergent as presence of lipid in the outer coat of rabies virus particle makes it relatively easy to disrupt them simply by addition of a lipid solvent.

As rabies virus is highly neurotropic virus, it can infect any warm blooded animal including man. There seems to be a variation in the susceptibility of different animal species to the virus infection. Wild animals like fox, jackal, mongoose, etc. are highly susceptible compared to dogs, cats and domestic animals.

RESERVOIR

Two cycles of rabies exist, sylvatic and urban. Foxes, raccoons, skunks, jackals, mongooses, bats, etc., maintain the sylvatic cycle. Dogs, cats, cattle, horses, sheep, pigs, etc., maintain the urban cycle. The exposures are reported frequently by dogs and cats, sometimes by monkeys, horses, sheep, cows, buffaloes, donkeys, pigs, occasionally by elephants, camels, foxes, mongooses, jackals, bears, which may lead to rabies. But rabies deaths due to small rodents have not been reported.

TRANSMISSION

The followings are the modes of transmission of rabies infection: (1) bite, (2) scratch, (3) lick on damaged skin and intact mucous membrane by rabid animals, (4) organ transplant—cornea transplant mainly and (5) aerosol spread in bat infested caves. The commonest mode of transmission of virus to human population is the bite from infected dogs. Rabies virus can not penetrate intact skin. An old injury on the skin can also allow entry of virus. So contamination of broken skin with saliva of rabid animal by simple licking can be dangerous. Scratches by rabid animals are also considered another mode of transmission, which allow virus entry. Rabies virus can penetrate intact mucous membrane. Drinking of raw milk of infected cow, buffalo or goat is such an example. Contact of saliva of rabid animals in anal region or mouth cavity, i.e., moist mucous surfaces is also considered to be dangerous.

PATHOGENESIS

After entering the human body, the virus replicates in muscles around the wound. Then it gains access to nerve endings and starts traveling at the rate of 3 mm/hour towards central nervous system. The virus ascends passively in the axoplasm of the nerves and reach dorsal root ganglion where they again replicate and reaches the anterior horn cells of spinal cord and then spreads to neurons of the spinal cord. Once CNS is involved there is rapid and extensive replication of virus in brain and spinal cord. Initially some areas like hippocampus, hypothalamus and limbic system are predominantly involved.

CLINICAL FEATURES

Average incubation period varies between 3 weeks and 3 months. It is highly variable, may be as short as 4 days to as long as 3 years. The size of inoculum of virus and the bites in head and neck region due to proximity to brain, in hands due to excess innervations may have some significance in the early causation of the disease.

There are 2 distinct clinical forms, furious rabies and dumb rabies. *Furious type* is seen in 80% cases, characterized by symptoms related to spasms of gullet, namely hydrophobia, aerophobia and others aggressiveness leading to coma and death in 3–5 days after onset of symptoms. *Dumb* or *paralytic type* is seen in 20% cases characterized by progressive onset of ascending paralysis. The order of involvement is lower limbs, abdominal muscles, upper limb and thoracic muscles, followed by coma, respiratory failure and death which is delayed and patient may live little longer, sometimes as long as a month.

DIAGNOSIS

Diagnosis of rabies is mostly clinical as 80% of cases present with hydrophobia, aerophobia and aggressiveness. Antemortem diagnosis can be attempted by detection of viral antigen in saliva or CSF, corneal smear immunofluorescent examination, and detection of viral nucleic acid in saliva and CSF by reverse transcriptase (RT)-PCR analysis. Postmortem diagnosis by demonstration of Negri bodies within the brain sample is 100% pathognomonic of rabies. Serological assays to measure the presence of antibody to rabies virus have been used for decades and represent an extremely useful tool for diagnosis, epidemiology and measurement of an immunological response after vaccination. Conducting rabies serological testing in an appropriate and correct manner is a complicated procedure.

TREATMENT

Nursing care, symptomatic therapy with sedatives, analgesics, proper hydration and intensive therapy are some main steps of the treatment of rabies patients. Parenteral diazepam, lorazepam or midazolam can be given to reduce psychomotor excitation. Better result can be obtained if it is administered along with antihistaminic and analgesics. At the same time patient has to be protected from external stimuli such as draughts, noise or bright light. Dehydration is severe and dramatic in all cases due to aversion of drinking water, excessive sweating and salivation, which demands a special care for the water salt balance. Massive intravenous infusions are required in all the patients. Prednisolone and mannitol may be administered to the patients with high intracranial pressure. Respiratory and cardiac support may be given to alleviate the sufferings and ensure peaceful death to the victim. There are a few sporadic reports of recovering from rabies following such treatment.

Individuals who Come in Contact with Rabies Patients

Persons who come in contact with rabies patients or who nurse those patients or who handle saliva or secretions of rabies patients, must take a full course of anti-rabies vaccine. They must be very cautious that they are not accidentally bitten or the saliva of the patient does not come in contact with any fresh cut, abrasions or mucous membranes of their body.

PREVENTION

Clinical categorization of rabies exposure as per WHO recommendation is a useful tool to treat an animal exposure case (**Table 1**). A transdermal wound in any place of the body or a mucous membrane contamination with saliva is to be dealt most seriously. Majority of wounds and exposures are of category III type. The following protocol is effective for prevention of rabies in a fresh exposed case irrespective of the fact of extension of exposure or the animal concerned. The steps are described below.

Step 1 Local washing of the wound thoroughly with soap and water. This step invariably reduces the virus load of the wound physically (running water) and inactivating the remaining particles of virus chemically (soap or detergent).

Step 2 Application of 70% alcohol, tincture of iodine, povidone iodine, or any other suitable disinfectant after removing all traces of soap, alcohol and other disinfectants. This leads to further

inactivation of remaining virus by chemical disruption. The animal bite wounds should not to be covered. Suturing of the wound should be avoided. When the suturing is unavoidable for the purpose of hemostasis, it must be ensured that immunoglobulins have been administered in the wound(s) prior to suturing.

Step 3 Proper infiltration of the wound(s) with rabies immunoglobulins (RIG) of human (HRIG) or equine (ERIG) origin. The dose of HRIG is 20 IU/kg of body weight and that of ERIG is 40 IU/kg of body weight. Skin test for sensitivity is not essential either for HRIG or ERIG. RIGs are specific rabies virus neutralizing antibodies that immediately neutralize rabies virus on contact. RIG gives a coating to the virus so that it cannot enter the nerve endings resulting reduction or total obliteration of inoculated virus.

The RIG should be infiltrated thoroughly into and around the wound. The remaining portion of the calculated amount of the RIG if any is to be injected in the deltoid region in older children and adults or anterolateral surface of thigh in newborns, infants and smaller children away from the site of vaccine administration to prevent onsite neutralization of vaccine antigen. If the administration of the RIG is delayed initially it can be administered up to 7th day after the 1st dose of vaccine, i.e., along with 3rd dose of vaccine, but in a separate site.

Step 4 Vaccination against rabies. It is advisable to administer a potent modern tissue culture rabies vaccine (MTCV) following an approved schedule which results in production of systemic antibodies against rabies after a lag period of 7–14 days from the 1st dose of ARV.

Antirabies Vaccines

The use of nerve tissue vaccines is now abandoned in India after the Supreme Court ruling. *Duck embryo vaccine* is presently available as purified duck embryo cell vaccine (PDEV). The purified duck embryo cell vaccine is claimed to be as immunogenic as the modern tissue culture vaccines. *Modern tissue culture vaccines* are now considered as the gold standard in rabies prevention. These vaccines are safe, potent and convenient to use. Three types of MTCV are available in India. Those are: (1) purified chick embryo cell vaccine (PCEC), (2) human diploid cell vaccine (HDCV) and (3) purified Vero cell vaccine (PVRV).

Schedules of Vaccinations Against Rabies

Intramuscular Regimens

Essen protocol (Table 2)—The WHO standard schedule commonly known as *Essen Protocol* comprises 5 IM injections on days 0, 3,

Table 1 WHO recommendations for management of animal bites

Category	Type of contact with suspected or confirmed domestic or wild animals* or animal unavailable for observation	Recommended treatment
I	Touching or feeding of animals, licks on intact skin	None, if reliable case history is available
II	Nibbling of uncovered skin, minor scratches or abrasions without bleeding, licks on broken skin	Administer vaccine immediately.** Stop treatment if animal remains healthy throughout an observation period of 10 days,*** Or, if the animal is euthanized and found to be negative for rabies by appropriate laboratory technique
III	Single or multiple transdermal bites or scratches, contamination of mucous membrane with saliva (i.e., licks)	Administer rabies immunoglobulins and vaccine immediately,** Stop treatment if animal remains healthy throughout an observation period of 10 days,*** Or, if the animal is euthanized and found to be negative for rabies by appropriate laboratory techniques.

*Exposure to rabbits, rodents and hares seldom if ever requires specific antirabies treatment

**If an apparently healthy dog or cat in or from a low risk area is placed under observation it may be justified to delay specific treatment

***This observation applies only to dogs and cats.

Table 2 Essen protocol (IM Schedule) for postexposure prophylaxis of rabies

	Days of vaccination					
	Day 0	Day 3	Day 7	Day 14	Day 28	Day 90
No. of doses	1 IM dose	1 IM dose	1 IM dose	1 IM dose	1 IM dose	Dose optional

7, 14, 28 or 30. The 6th dose on day 90 is optional which is administered in selected cases like in extremes of ages, with debility and protein energy malnutrition, in immunocompromised patients, with neoplastic diseases, undergoing antimalarial treatment, suffering from viral hepatitis, presently taking steroid containing drugs for long time, etc. This schedule is practiced in our country as we are in the highest endemic zone of rabies.

Intradermal Schedules

2-2-2-0-1-1 ID schedule (Thai Red Cross ID schedule or TRC-ID schedule) (Table 3)—Two ID doses given on day 0, day 3 and day 7 on two deltoids, one ID dose on one site of deltoid on day 28 and 90. No dose is given on day 14. One ID dose is 1/5th of quantity of IM dose depending on vaccine though 0.1 mL of purified chick embryo cell vaccine is also used successfully in community practice. But the ID schedule is recommended only for the centers where at least 10 antirabies vaccines are given in a day, otherwise there will be wastage of vaccine.

Pre-exposure Schedule

Pre-exposure vaccination Rabies is the infectious disease where active immunization is administered after the exposure. This group of vaccination is termed as postexposure vaccination. But it is possible to administer pre-exposure vaccination to protect individuals at risk of rabies even before the exposure has occurred, namely, to the veterinary doctors, municipal workers, postmen and women, taxidermists, laboratory and research workers in the field of rabies, dog handlers, etc.

Intramuscular (IM) pre-exposure schedule Three IM doses are to be given on days 0, 7 and 21 or 28 intramuscularly. A booster dose is needed after 1 year of 1st dose and then booster doses every 3 yearly to keep an effective antibody titer against rabies.

Intradermal (ID) pre-exposure schedule Now a days 0.1 mL ID of MTCV doses are also accepted scientifically as pre-exposure doses on days 0, 7, 28 then 0.1 mL ID dose of MTCV every year.

Table 3 Thai Red Cross-intradermal (ID) Schedule (2-2-2-0-1-1) for postexposure prophylaxis of rabies

	Days of vaccination					
	Day 0	Day 3	Day 7	Day 14	Day 28	Day 90
No. of doses	2 ID doses in 2 separate sites	2 ID doses in 2 separate sites	2 ID doses in 2 separate sites	No dose	1 ID dose	1 ID dose

1 ID dose = 1/5 of IM dose both in PBRV and PCEC
Only for community practice 0.1 mL of PCEC per dose is also used.

Adverse Reactions of MTCV

The tissue culture rabies vaccines are safe and well tolerated. Mild local effects such as pain, redness and swelling may be observed in 10–20% of the recipients. Systemic manifestations such as fever, malaise, headache, abdominal pain may be seen transiently in a few vaccines and can be minimized by the use of anti-inflammatory drugs. Very rarely immune complex reactions and neurological illness resembling Guillain-Barré syndrome have been reported in temporary association with HDCV.

Revaccination for Repeat Exposures in Previously Vaccinated Persons

There is no need of RIG administration during the repeat exposure when there is past history of complete pre- or postexposure vaccination. The recommendation is to repeat vaccinations with 2 booster doses, one on day 0 and other on day 3 if there is history of complete postexposure or pre-exposure treatment previously within 3 years. Any exposure after 3–5 years of vaccination, are treated with complete postexposure vaccination excluding RIG administration in our country.

IN A NUTSHELL

1. India is a high endemic country for rabies.
2. Modes of transmission are bite, scratch, lick on damaged skin, intact mucous membrane and organ transplant. After entering the human body, the virus replicates in muscles around the wound and then it gains access to nerve endings and starts traveling.
3. Two distinct clinical forms exist—furious rabies and dumb rabies. The former is seen in 80% cases, characterized by hydrophobia, aerophobia and aggressiveness.
4. Rabies is almost 100% fatal but 100% preventable.
5. Local washing of the wound thoroughly with soap and water reduces the virus load.
6. Proper infiltration of the wound(s) with rabies immunoglobulins should be done in all WHO category III exposure.
7. Modern tissue culture vaccines are effective in postexposure and pre-exposure rabies prevention.

Chapter 31.11

Japanese Encephalitis

Rashmi Kumar, Piyush Tripathi

Japanese encephalitis (JE) is the single largest cause of viral encephalitis in the world today with a reported 45,000 cases, 10,000 deaths and 15,000 survivors left with disability annually. This too is very likely an underestimate due to lack of diagnostic facilities and surveillance systems in regions affected. The disease is endemic in several states in India with frequent outbreaks in eastern UP, Bihar, West Bengal, Assam and Andhra Pradesh with large number of morbidity and mortality among children under 15 years of age.

HISTORY AND DISTRIBUTION

Japanese encephalitis is mainly an Asian disease. Summer epidemics of encephalitis occurred in Japan as far back as the 1870s. In 1935 the virus was isolated from a fatal human case. Since that time it spread to most of South East Asia and its presence is being increasingly recognized in this region and also the Western Pacific islands and northern Australia. Presently JE is reported from 25 countries—Australia (Torres Strait Islands), Bangladesh, Bhutan, Brunei, Burma, Cambodia, China, India, Indonesia, Japan, North Korea, South Korea, Laos, Mongolia, Nepal, Pakistan, Papua New Guinea, Philippines, Russia, Singapore, Sri Lanka, Taiwan, Thailand, Timor-Leste, Vietnam, and western Pacific islands. In India, the disease was first recognized in the 1950s from Vellore. The first large epidemic occurred in West Bengal (Bankura district) in 1973. Since then it is endemic in southern and eastern states with monsoon and post monsoon outbreaks. It is also showing a westward trend and presently human cases are reported from all states except Dadra, Daman, Diu, Gujarat, Himachal Pradesh, Jammu and Kashmir, Lakshadweep, Meghalaya, Nagar Haveli, Punjab, Rajasthan and Sikkim.

THE VIRUS

The Japanese encephalitis virus (JEV) is a single stranded positive sense neurotropic RNA virus belonging to the *Flavivirus* genus, family *Flaviviridae*. It is closely related to other flaviviruses like dengue, chikungunya, St Louis encephalitis, Murray Valley encephalitis, tick borne encephalitis and yellow fever. In fact there is cross reactivity between flaviviruses.

The JE virion RNA is wrapped in a nucleocapsid and surrounded by a glycoprotein containing envelope. There are 3 structural proteins—pre membrane (PrM), core (C) and envelop (E), and 7 nonstructural proteins (NS1, NS2A, NS2B, NS3, NS4A, NS4B, NS5). The E protein is the largest structural protein related to neurovirulence and is the main target for humoral immune response. There are 5 genotypes I to V, based on the nucleotide sequence of the envelop (e) gene. Genotype I and III were found mainly in northern temperate *epidemic* regions and genotypes II and IV were found in southern *endemic* regions. Japanese encephalitis virus genotype V was first reported from Malaysia in 1952 (Muar strain) and re-emerged after a 57-year hiatus in Asia (China) in 2009. Until 2007, all known Indian JEV strains belonged to G III. However, recently, G I has been isolated from the Gorakhpur region, India.

NATURAL CYCLE

Japanese encephalitis is a zoonosis and the virus circulates in nature between the vector and vertebrate hosts. The main vector all over Asia is the *Culex tritaeniorhynchus*—a zoophilic rice field breeding

mosquito. Other vectors like *C. vishnui*, *C. pseudovishnui* and some anopheles mosquitos are also known. The main vertebrate hosts all over Asia are the pig and birds of the family Ardeidae. These hosts have significant viremia and therefore are able to harbor, amplify and transmit the virus without developing illness, although the cycle may get aborted in pigs. Man is only an incidental dead-end host with very short viremia which does not allow further transmission. Cattle do not have significant viremia and do not develop disease but can support a large population of mosquitos.

EPIDEMIOLOGY

This is explained by the natural cycle as the disease occurs in poor rural folk in rice growing areas where pig rearing is common. Japanese encephalitis tends to occur in epidemics and outbreaks which coincide with peak mosquito activity. Two main patterns of occurrence are seen. In *northern* regions it occurs as summer epidemics while in southern regions it is endemic with monsoon/postmonsoon peaks. It is primarily a disease of children of 5–15 years age and young adults, incidence being 1–10 per 10,000 in affected areas. When a new nonimmune population is involved, adults are also commonly affected. There is a scattered pattern of incidence with only 1–2 cases occurring per village and some villages are completely spared. A study of laboratory proven cases of JE in children hospitalized during the 2005 epidemic in Uttar Pradesh, India revealed that children below 2 years of age were not affected, boys accounted for three fourths of the cases and almost all patients hailed from rural areas.

PATHOGENESIS

Factors which determine the course of infection include agent factors—titer of inoculum, strain virulence and route of entry, and host factors—age, genetic makeup, immunity and general health. The JEV E protein plays a major role in virulence phenotype; even single amino acid substitutions may cause loss of neuroinvasiveness.

Japanese encephalitis virus enters the body through a mosquito bite, multiplies within host leukocytes (probably T lymphocytes) and is carried to the central nervous system (CNS). The virus particles bind to the endothelial surface of the brain blood vessels and are internalized by endocytosis. Damage in flaviviral encephalitis appears to result both from direct virally mediated damage as well as host inflammatory response. Microglial cells undergo uncontrolled overactivation, releasing proinflammatory cytokines. This promotes massive leukocyte migration and infiltration in the brain. Recently, apoptosis has been shown in vitro in different cell lines for various arboviruses. IgM antibody and T lymphocytes play a major role in the clearance of the virus after infection. Pre-existing ant flaviviral antibodies may protect against severe disease.

PATHOLOGY

The brain bears the brunt of the infection. There is swelling and intense congestion of the gray matter with confluent areas of hemorrhage. A characteristic but not pathognomonic finding is focal punched out areas of necrosis in the gray matter. Infiltration of meninges and perivascular areas with mononuclear cells is seen. The cerebral cortex shows microglial infiltration with circumvascular necrotic zones with total loss of neurons, whereas the white matter is fairly well-preserved.

CLINICAL FEATURES

Japanese encephalitis virus infection can be asymptomatic or can cause an acute undifferentiated febrile illness or meningo-

cephalitis. Like most other viral meningoencephalitides, the course of JE can be divided into three stages—(1) *prodromal stage* with nonspecific fever, headache, vomiting, diarrhea, etc., lasting from a few hours to days; (2) *acute encephalitic stage* with continuing fever, convulsions, coma and signs of raised intracranial tension lasting 7–10 days and; (3) *convalescent stage* with gradual improvement over weeks to months. In severe cases signs of raised intracranial tension, hyperventilation, shock and death may occur in quick succession. A study on 77 laboratory confirmed cases showed mean prodromal stage of 2.6 (SD = 2.23) days, convulsions in 98.7%, mean Glasgow Coma Scale on admission of 7.4 (SD = 2.7), focal neurological deficits in 45.4%, extrapyramidal signs in 31.1%, hyperventilation in 26%, gastric hemorrhage in 54.5% and early mortality of 34%. A study to identify clinical features of JE to differentiate it from other similarly presenting illnesses revealed that hyperventilation in the acute stage and extrapyramidal features were significant independent predictors of the diagnosis.

Sequel A follow-up study on 55 laboratory confirmed cases showed that major sequelae (frank intellectual disability, frank motor deficits or epilepsy) were present in 45.4% and another 25% had minor sequelae (behavioral disturbances, scholastic backwardness or subtle neurological signs) after more than 1 year. Less than 30% were normal. JE can also cause lower motor neuron paralysis possibly due to myelitis.

DIAGNOSIS

A neutrophil leukocytosis is seen in the peripheral blood in most cases. Cerebrospinal fluid (CSF) examination may reveal a normal cell count or mild to moderate pleocytosis with elevated protein but normal sugar. During the JE epidemic of 2005, half the children seen in Lucknow had normal CSF and in the remainder there was a mild pleocytosis. Maximum CSF cell count was 300/cu mm and only 12.3% patients had counts beyond 100/cu mm. Electrophysiological studies revealed EEG abnormalities in 80%, in the form of nonspecific θ - δ slowing, α coma, periodic lateralized epileptiform discharges and other epileptiform discharges or burst suppression. Muscle evoked potentials (MEP) were abnormal in 70%, correlating with weakness and poor 3 month outcome. Electromyograms and somatosensory evoked potentials (SSEP) also revealed abnormalities in a small proportion of patients.

Microbiological Diagnosis

For IgM detection, blood and CSF should be collected at least 5 days after the onset of illness. Serum, blood and CSF should be stored at 4–8°C and transported in ice to the laboratory. If testing is likely to be delayed beyond 1 week the sample can be stored at –20°C. However, repeated freezing and thawing is undesirable as it results in denaturation of antibody. Time since onset of illness should be mentioned on the sample. For isolation of virus and detection of viral genome by PCR, blood and CSF samples should be collected within 4 days after the onset of illness.

Earlier the diagnosis was confirmed by viral isolation from CSF or brain by intracerebral inoculation in infant mice followed by the quick complement fixation test. Hemagglutination inhibition test is done in paired sera taken 10–14 days apart but cross reactions occur with other flaviviruses and parallel testing needs to be done. The most widely used test is detection of JEV specific IgM by ELISA. The test is usually positive in CSF and serum by about 7 days of illness and has 95% sensitivity and specificity in CSF by 10 days of illness. If sample taken early in the illness is negative the test should be repeated around this time.

Viral isolation and detection of JEV genome is possible from CSF or brain early in the illness but the yield is low and cannot be used to rule out the diagnosis.

Radiological Features

Typical changes involve bilateral thalami, basal ganglia, putamen, pons, cerebellum and spinal cord. Magnetic resonance imaging (MRI) is more sensitive. In one study, computed tomographic scans (Fig. 1) were abnormal in 55% while MRI scans were abnormal in all. Association with neurocysticercosis is seen.

Figure 1 Computed tomographic scan image of a patient of Japanese encephalitis showing changes in thalamus and basal ganglia

DIFFERENTIAL DIAGNOSIS

A wide variety of disorders can mimic JE. These include other viral encephalitides—arboviruses, enteroviruses, Herpes group, myxoviruses, paramyxoviruses, adenoviruses, parvoviruses and rhabdoviruses, CNS invasion by nonviral agents, noninfectious inflammation—acute disseminated encephalomyelitis, antibody associated encephalitis, infectious encephalopathies (cerebral malaria, shigella encephalopathy, dengue encephalopathy, enteric encephalopathy and sepsis associated encephalopathy) and functional and structural causes of coma if associated with fever due to some other cause.

SURVEILLANCE

In 2006, recognizing the public health proportions of Japanese encephalitis in endemic regions, WHO coined the term acute encephalitis syndrome (AES) for surveillance purposes. Clinically, AES is defined as “a person of any age, at any time of year with acute onset of fever and at least one of: (1) change in mental status (including symptoms such as confusion, disorientation, coma, or inability to talk); (2) new onset of seizures (excluding simple febrile seizures). Other early clinical findings may include an increase in irritability, somnolence or abnormal behavior greater than that seen with usual febrile illness” WHO case classification of AES is depicted in Box 1.

The large majority of JE infections are asymptomatic. Therefore, in areas that are highly endemic for JE, it is possible to have AES due to a cause other than JE virus and have JE virus-specific IgM antibody present in serum. To avoid implicating asymptomatic JE as the cause of other AES illnesses, sterile collection and testing of a CSF sample from all persons with AES are recommended when feasible. During periods of epidemic transmission of JE virus, laboratory confirmation of every case may not be necessary.

BOX 1 WHO case classification of acute encephalitic syndrome (AES)

AES: a case that meets the clinical case definition of AES above. AES cases should be classified in one of the following 4 ways:

Laboratory confirmed JE: An AES case that has been laboratory confirmed as JE.

Probable JE: An AES case that occurs in close geographical and temporal relationship to a laboratory confirmed case of JE, in the context of an outbreak.

AES—other agent: An AES case in which diagnostic testing is performed and an etiologic agent other than JE virus is identified.

AES—unknown: An AES case in which no diagnostic testing is performed or in which testing was performed but no etiologic agent was identified or in which test results were indeterminate.

WHO Recommendations for JE Surveillance

According to WHO, “When feasible, surveillance should be performed within the context of integrated disease surveillance and linked with similar surveillance activities such as those for acute flaccid paralysis or meningitis. JE surveillance should be conducted year round. Two types of surveillance are recommended:

1. *In all Asian countries* Comprehensive syndromic surveillance for acute encephalitis syndrome (AES) with aggregate reporting is recommended. In sentinel hospitals, surveillance should be case based with specimens collected for laboratory confirmation. The number of sentinel hospitals should be gradually increased if feasible.
2. *In Asian countries where a high level of JE control has been achieved* surveillance should be case based throughout the country and include laboratory confirmation of all suspected cases.

Regardless of the type of surveillance, reporting should be weekly or monthly and include *zero-reporting* (i.e., no blanks should be left in the reporting forms, a zero should be indicated when there are no cases detected). Outbreak investigations should be initiated if there is a sudden increase in cases or if cases reported are different from historical information, in terms of season, geographical area, age group, or case fatality.”

TREATMENT

Treatment of JE is essentially supportive. A severe case should be managed in an intensive care setting with careful monitoring,

maintenance of homeostasis and good nursing care. Antipyretics and anticonvulsants should be given as necessary. Measures to reduce intracranial tension such as mannitol infusions, glycerol, acetazolamide and positive pressure ventilation to maintain arterial carbon dioxide between 25 mm Hg and 30 mm Hg may be required. No specific antiviral treatment has shown benefit in randomized controlled trials. A study of interferon α in Vietnamese children failed to show benefit as did another trial of oral/nasogastric ribavirin in Indian children. Steroids also have not shown benefit. Recently the tetracycline drug minocycline has been shown to accord complete protection against JE in mouse model.

PREVENTION

Control of JE can be directed to control of the vector through insecticide spray, larvicides, bed nets, repellants, and in the long-term, better water management. Measures against the vertebrate host include vaccination of pigs and location of piggeries away from human dwelling. The most effective method of JE control is through vaccination (**Table 1**) of the human host. It must be realized though, that human vaccination does not interrupt the natural cycle of the virus, does not prevent transmission of the virus in nature and there is no herd immunity. An unvaccinated individual therefore remains susceptible to the infection. A JE control target of 0.5 confirmed JE cases per 100,000 children under 15 years of age in affected countries by 2015 has been set by PATH (2009).

Mouse Brain Killed Vaccine

This is the earliest vaccine to be manufactured against JE, originally produced by BIKEN, Japan and marketed in the US as JE-VAX. It was also produced in India at Kasauli. Since the vaccine was derived from neural tissue, a risk of neurological events did exist. Booster doses were required. A new pattern of adverse reactions in the form of urticaria, angioedema, respiratory distress and collapse due to hypotension were reported since 1989, mostly among travelers. All this led to suspension of vaccine production and all remaining doses expired in 2011.

P3 Strain Vaccine

This is a formalin inactivated, cell culture-derived, JE vaccine based on the Beijing P-3 strain. The vaccine was in wide use in

Table 1 Vaccines for Japanese encephalitis

Vaccine	Schedule	Dose	Remark
Mouse brain killed vaccine	2 doses up to 4 weeks apart	0.5 mL for children aged 1–2 years; 1.0 mL for children aged 3 years and older	Expensive, short supply, adverse effects, production stopped
P3 inactivated vaccine	2 doses and booster every 3 years	0.5 mL for 6–12 months of age, then boosters at 1 year, school entry, and at the age of 10 years	Low immunity, need for boosters
Live attenuated vaccine	Single dose/2 doses 1 year apart	0.25 mL for 2 months through 3 years, 0.5 mL for 3 years of age and older	Good immunity even after 5 years; WHO prequalified in 2013
Ixiaro	2 doses 28 days apart and booster after 1 year	0.25 mL for 2 months–2 years, 0.5 mL for 3–16 years of age and 0.5 mL for ≥ 17 years of age	Full duration of protection after primary immunization is unknown
Vero cell-derived purified inactivated JE vaccine from Indian strain of the virus (821564 XZ)	2 doses up to 4 weeks apart starting from 1 year of age.	0.5 mL each	Since appreciable waning was noted in both seroconversion and seroprotection rates, there is definitely a need of booster dose at later stage
Chimeric vaccine			Premembrane and envelop (prME) genes of an attenuated human vaccine strain (SA-14-14-2) of JE virus inserted between core and nonstructural genes of a Yellow Fever 17D infectious clone. Phase III trials underway

China since the 1960s. The relatively low efficacy and need for repeated booster doses led to the vaccine being replaced by the live attenuated vaccine.

Live Attenuated Sa-14-14-2 Strain Vaccine

This is the only live attenuated JE vaccine currently available. It is being used in the public sector in China since 1998, Nepal (since 1999) and India (since 2006). Studies conducted in Nepal reported efficacy of 99.3% in the same year, 98.5% after 1 year and 96.2% after 5 years. An Indian study found vaccine efficacy to be 94.5% after 6 months. Adverse effects are seen in only 5–10% recipients—transient fever, local reactions, rash or irritability. This vaccine was imported by the Government of India from China after the Uttar Pradesh epidemic of 2005. It was used in campaign style vaccination drives for children 1–15 years of age in Uttar Pradesh and later incorporated in the national immunization program. Dose is 0.5 mL given subcutaneous. The initial vaccine strain did not meet WHO prequalification standards but recently this vaccine manufactured in China in partnership with global health organization PATH has met WHO prequalification standards.

IC51 Vaccine–Ixiaro

This is a new generation formalin inactivated vaccine manufactured by Intercell (Austria) and distributed by Novartis Vaccines. It is prepared from the SA-14-14-2 strain grown in Vero cells. This is the only JE vaccine to have received US Food and Drug Administration (FDA) approval for use in adults 17 years of age or older in 2009 and children beyond 2 months age since 2013. This vaccine was licensed in the US on the basis of its ability to induce JE virus neutralizing antibodies as well as safety evaluations in almost 5,000 adults. Protective neutralizing antibodies developed in 96% of adults after schedule of 2 doses 28 days apart. Local symptoms of pain and tenderness were the most commonly reported symptoms in a safety study with 1,993 adult participants. Post licensure studies and surveillance are ongoing to further evaluate the safety of Ixiaro in a larger population. This vaccine is available in India as JEEV (Biological E Ltd). Schedule is 2 doses 28 days apart followed by a booster after 1 year. Dose is 0.25 mL below 3 years and 0.5 mL beyond.

Indian Strain Vaccine

Another Vero cell-derived purified inactivated JE vaccine is developed from an Indian strain of the virus (821564 XZ) isolated in Kolar, Karnataka, during the early 1980s and characterized by the National Institute of Virology, Pune. This vaccine was developed through public-private partnership between the Indian Council of Medical Research and Bharat Biotech Ltd. It has received manufacturing and marketing approval from the Drug Controller General of India. It is being marketed by the name JENVAC.

Chimeric Vaccine

Live attenuated chimeric JE vaccine using SA14-14-2 strain and yellow fever 17 D virus has been developed and undergone trial in India. The premembrane and envelop (prME) genes of an attenuated human vaccine strain (SA-14-14-2) of JE virus are inserted between core and nonstructural genes of a YF 17D infectious clone, resulting in a live chimeric vaccine.

World Health Organization. Japanese encephalitis vaccines. *Weekly Epidemiological Record*. 2006;81:331-40.

IN A NUTSHELL

1. Japanese encephalitis, the single largest cause of viral encephalitis in the world today, is primarily an Asian disease.
2. It occurs in annual outbreaks in most of southern and eastern India.
3. Japanese encephalitis is a zoonosis with its natural cycle in the mosquito vector and vertebrate hosts. Man is an incidental dead end host. The main vector is the *Culex tritaeniorhynchus*—a rice field breeding mosquito and the main vertebrate hosts are pig and ardeid birds.
4. The JEV is a single stranded positive sense neurotropic RNA virus with 3 structural proteins—premembrane (PrM), core (C) and envelop (E), and 7 nonstructural proteins. The E protein is related to neurovirulence. There are 5 genotypes and genotype III is most prevalent in India.
5. The clinical course of JE can be divided into 3 stages—(1) prodromal stage with nonspecific fever, headache, vomiting, diarrhea etc, lasting from a few hours to days; (2) acute encephalitic stage with continuing fever, convulsions, coma and signs of raised intracranial tension lasting 7–10 days and; (3) convalescent stage with gradual improvement over weeks to months. About 70% of survivors suffer sequelae.
6. Diagnosis is mainly by detection of JE IgM in cerebrospinal fluid or serum. Radiological features are hypodensities in thalami, basal ganglia and brain stem.
7. Differential diagnosis includes other viral encephalitides, nonviral meningoencephalitides, immune mediated encephalitis, infectious encephalopathies and functional and structural causes of coma.
8. Treatment is largely supportive.
9. WHO has coined the term *acute encephalitis syndrome* for surveillance purposes and has set surveillance standards for JE.
10. The mainstay of prevention is through vaccination. Both live and killed vaccines derived from the SA-14-14-2 strain are available. The killed vaccine grown in Vero cells has received FDA approval for use in travelers. An Indian strain killed vaccine is also available.

Chapter 31.12

Infectious Mononucleosis

Rashmi Ranjan Das

Infectious mononucleosis (IM) refers to a spectrum of clinical manifestations caused by Epstein-Barr virus (EBV), and is variably named as *Glandular fever* or *Kissing disease*. The illness commonly affects the children and adolescents. The characteristic features are prolonged fever, pharyngitis, lymphadenopathy, fatigue, myalgia and atypical lymphocytosis. Infectious mononucleosis is named because of the mononuclear lymphocytosis with atypical lymphocytes that accompany the clinical syndrome.

EPIDEMIOLOGY

The epidemiologic factors that influence the incidence and distribution of infection by EBV differ from those that cause clinical IM. The two main factors influencing infection are: levels of hygiene and cultural patterns, leading to exposure to saliva. In developing countries, pre-chewing of food for infants, and in developed countries, oral kissing in adolescent period are important modes of transmission of infection. Besides oral route, parenteral routes (blood transfusion and bone marrow transplantation) also play a role in transmission of infection. Epstein-Barr virus does not spread through environmental sources, droplets, fomites or sexual contact. The factors influencing development of IM are: age at the time of exposure, immune status, genetic factors, and psychosocial variables. Epstein-Barr virus infection without clinical IM occurs early in life in developing countries, but clinical IM is common in developed countries because of delayed exposure and infection until older childhood or young adult life.

In developing countries, most children under 5 years of age are infected with the immunity reaching almost 100% by the age of 10 years. In a study from India, IM was found to be more common during the preschool age. After acute infection, the virus is shed continuously in oral secretions for more than 6 months, followed by intermittently for life. The rate of viral shedding varies from 20–30% in healthy patients to as high as 60–90% in immunosuppressed patients. Infectious mononucleosis does not show seasonal variation.

ETIOLOGY

Infectious mononucleosis is caused by EBV, a DNA virus of the herpes family. Epstein-Barr virus causes both heterophile-positive and most of the cases of heterophile-negative IM. An infectious mononucleosis like syndrome (IMLS) may be caused by both infectious (infection due to *Cytomegalovirus*, HIV, human herpes virus 6, adenovirus, rubella, toxoplasma, *Streptococcus*, brucellosis, spirochetes, and *Salmonella*), and noninfectious conditions (drugs, autoimmune, and neoplastic diseases).

PATHOGENESIS

The EBV enters the oropharynx through salivary fluid transfer, either by kissing in adolescents or saliva-contaminated objects in children. The virus multiplication occurs locally in the epithelial cells of parotid duct, oropharynx, tongue and salivary gland tissue. This leads to an exudative pharyngotonsillitis along with sore throat. Viral multiplication in the local lymphatics often results in cervical lymphadenopathy. The virus then enters the bloodstream from one of these sources, involves B cells (through CD21 receptors), and spreads hematologically to different organs producing pertinent

clinical manifestations. Atypical lymphocytosis occurs in response to infected B cells. These are CD8⁺ T cells that exhibit both cytotoxic suppressor functions and are characteristic features of IM. This results in an inverted CD4⁺/CD8⁺ T cell ratio. The memory B cells act as reservoir of the virus in the body.

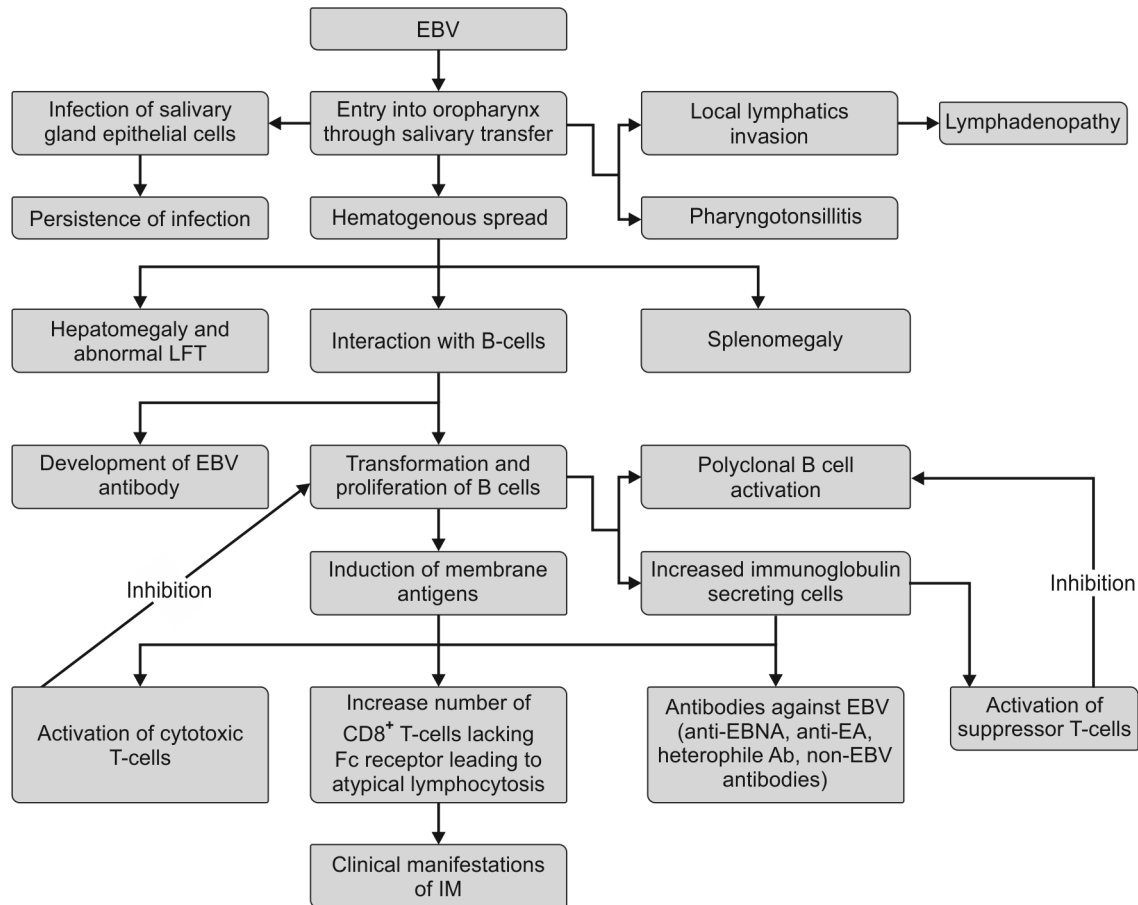

The postulated mechanisms behind development of the clinical features of IM are: B and T cell interactions, immune complex deposition or other immunopathologic events, direct effect of the virus on cells or from combination of some of these mechanisms. The rare occurrence of IM during early childhood may be because of the failure to evoke induction of neoantigens on the B-cell surface, by the virus. In older children and young adults, the T cells that respond to such neoantigens are composed largely of proliferating CD8⁺ T cells that lack the Fc receptor for IgG and IgM. Some of these T cells are cytotoxic and lyses infected cells, limiting their proliferation and accounting for the low percentage of virus-positive B cells during the acute phase of IM. The acute illness and the proliferation of B cells are limited in part by both nonspecific and antigen-specific cytotoxic T cells, along with the lymphokines they produce, and the humoral antibody.

A single attack of IM confers a high degree of durable immunity, and the second infection either occurs very rarely or not at all. As the subclinical or inapparent EBV infections confer lasting immunity, the classic disease occurs rarely. However, if the T cell immunity is compromised, endogenous reactivation occurs and the virus infected B cells may start proliferating leading to the development of clinical syndrome. The pathogenesis has been described schematically in **Flow chart 1**.

CLINICAL FEATURES

The exact incubation period of IM in children is not known, but may be shorter than the 4–8 weeks period seen in adolescents. Nonspecific features like malaise, fatigue, and myalgia for 1–2 weeks may precede the onset of fever, sore throat/pharyngitis, and lymphadenopathy. Low-to-moderate degree of fever commonly occurs in the first 2 weeks of the illness, sometimes persisting for more than 1 month. Sometimes, the fever may be associated with chills and rigors, thus mistaken as malaria in the initial period. Infectious mononucleosis is also one of the common causes of pyrexia of unknown origin (PUO). The pharyngitis is often associated with whitish or gray-green exudates having an offensive odor. The eyelids may be swollen, and petechiae occur on the hard palate in 5–7% cases.

The median frequency of symptoms is as follows: sore throat (75%), malaise (47%), headache (38%), abdominal pain, nausea or vomiting (17%) and chills (10%). The median frequency of signs is as follows: lymphadenopathy (95%), fever (93%), pharyngotonsillitis (82%), splenomegaly (51%), periorbital edema (13%), hepatomegaly (11%), rash (5%) and jaundice (5%). Deranged liver function tests occur as a common finding but symptomatic hepatitis or jaundice is rare. In the first and second week of illness, pharyngotonsillitis and lymphadenopathy are most prominent. In the second and third week of illness, splenomegaly is more prominent. Though posterior cervical lymph nodes are most commonly affected, generalized lymphadenopathy sometimes occur in IM. The lymph nodes are enlarged, symmetrical, may or may not be tender and are neither matted nor fixed. Epitrochlear lymphadenopathy has also been described with relatively increased frequency. In approximately 5% cases, a morbilliform or papular erythematous rash develops on upper extremities or trunk. One of the characteristic features is the development of *ampicillin rash* after administration of ampicillin or amoxicillin in 80% cases. This rash is vasculitic in nature developing secondary to immune complex deposition, and resolves spontaneously without treatment.

Flow chart 1 Proposed pathogenesis of EBV leading to infectious mononucleosis

Abbreviations: LFT, liver function test; Ab, antibody; EBNA, Epstein-Barr nuclear antigen; EA, Epstein-Barr early antigen; EBV, Epstein-Barr virus; IM, infectious mononucleosis.

COMPLICATIONS

Few patients with IM experience complications in the initial 2 weeks of illness. Complications that can lead to death are those related to: upper airway obstruction, central nervous system, splenic rupture and septic shock (bacterial superinfection). In one study, children having fever for more than 14 days were at an increased risk of complications, and septic shock was common in those having high VCA-IgM antibody titer. The rate of splenic rupture in children is probably much lower than the adult rate of less than 0.5%. The rupture is either spontaneous or preceded by trivial trauma. There may be marked swelling of the oropharyngeal lymphoid tissue and tonsils causing airway obstruction manifest as breathing difficulty and/or stridor. Though uncommon (incidence is <5%), it is one of the most common indications for hospitalization.

DIFFERENTIAL DIAGNOSES

Though EBV causes most of the heterophile positive and negative cases of IM, infectious mononucleosis like syndrome (IMLS) is caused by cytomegalovirus (CMV), toxoplasma, adenovirus, viral hepatitis, HIV or other agents. Cytomegalovirus causes most of the heterophile negative mononucleosis syndromes. Compare to classic IM, IMLS is associated with a lower frequency of lymphadenopathy, pharyngotonsillitis and splenomegaly. Streptococcal pharyngitis is the most common differential diagnosis, and any failure of improvement within 48–72 hours

of treatment should raise suspicion of IM. The differential diagnoses are summarized in **Table 1**. When complications like extremely high or low total leukocyte counts, moderate-to-severe thrombocytopenia, and hemolytic anemia occurs, a thorough investigation including bone marrow examination is justified to exclude any serious underlying cause. Other rare differential diagnoses include infections (due to human herpes virus 6, rubella, *Brucella*, spirochetes, and *Salmonella*), drugs, autoimmune diseases and neoplastic conditions (lymphoma or leukemia).

DIAGNOSIS

The accuracy (sensitivity and specificity) of clinical parameters used for the diagnosis of IM is summarized in **Table 2**. The two most important parameters that are useful in considering the possibility of IM are splenomegaly and lymphadenopathy (involving posterior cervical, axillary and inguinal lymph nodes), and in ruling out the possibility of IM are: absence of cervical lymphadenopathy and fatigue. *Hoagland's diagnostic criteria* have been widely used. Though highly specific, these criteria are not highly sensitive making them useful only for research purposes. The criteria include following parameters: lymphocytosis (50% of differential counts with 10% being atypical lymphocytes) *plus* fever, lymphadenopathy and pharyngitis *plus* a positive serological test.

Routine Laboratory Tests

Hemoglobin is normal (anemia is rare in IM). The total leukocyte count is commonly increased to the range of 10,000–20,000/mm³, of which more than 60% are lymphocytes (atypical lymphocytes

Table 1 Differential diagnosis of infectious mononucleosis like syndrome (IMLS) with key features

Causes of IMLS	Differentiating features
Viral pharyngitis (influenza, adenovirus)	Fever, lymphadenopathy, and tonsillar exudate are less common, but cough and rhinorrhea are more common. Splenomegaly and palatal petechiae are unlikely. ESR normal.
Streptococcal pharyngitis	Lymphadenopathy is usually anterior cervical and submandibular, compared to posterior cervical in IM. Fatigue and malaise is less prominent. Splenomegaly and palatal petechiae are unlikely. ESR normal. Responds to antibiotics in 48–72 hours.
Cytomegalovirus infection	Fever, lymphadenopathy, tonsillar exudate are less common. During acute illness, significant elevation in IgM or a fourfold increase in antibody IgG titers in paired sera.
Toxoplasmosis	Fever, lymphadenopathy, tonsillar exudate are less common. During acute illness, significant elevation in IgM or a fourfold increase in antibody IgG titers in paired sera.
Acute human immunodeficiency virus infection	Opportunistic infections, skin rash, weight loss, nausea, vomiting, diarrhea, low CD4 ⁺ T cell count

Table 2 Accuracy of clinical parameters in the diagnosis of infectious mononucleosis

Clinical parameters	Sensitivity (%)	Specificity (%)
Splenomegaly	7	99
Any cervical lymphadenopathy	87	58
Anterior cervical lymphadenopathy	70	43
Posterior cervical lymphadenopathy	40	87
Axillary lymphadenopathy	27	91
Inguinal lymphadenopathy	53	82
Fever	27	84
Fatigue	93	23
Headache	60	55
Palatal petechiae	27	95

Table 3 Serological features of infectious mononucleosis

Phases of illness	Heterophile Ab (Paul-Bunnell, Monospot)	Anti-VCA Ab		Anti-EA Ab		
		IgM	IgG	EA-Diffuse	EA-Restricted	Anti-EBNA Ab (IgG)
Acute phase	+	+	++	+	–	–
Convalescent phase	±	–	+	–	±	+
Past infection	–	–	+	–	–	+
Reactivation or chronic active phase	–	–	++	+	+	±

Abbreviations: Ab, antibody; VCA, viral capsid antigen; EA, early antigen; EA-D, antibody to EA in diffuse pattern; EA-R, antibody to EA in restricted pattern; EBNA, Epstein-Barr nuclear antigen.

being around 20–40%). Thrombocytopenia with the platelet count in the range of 50,000–150,000/mm³ occurs in more than 50% of patients but clinical bleeding (petechiae or purpura) is rare. Erythrocyte sedimentation rate might be elevated. Deranged liver function test commonly manifesting as transaminitis with normal or slightly increased bilirubin occurs in 50% of uncomplicated cases, but clinical jaundice is rare.

Heterophile antibody test Heterophile antibodies commonly occur in the sera of patient affected with IM. Two tests are commonly employed to detect them: *Paul-Bunnell test*—the sheep red blood cells (RBCs) agglutinate in the presence of heterophile IgM antibodies, and *Monospot test (latex agglutination assay)*—the horse RBCs agglutinate in the presence of heterophile IgM antibodies. Monospot test has a sensitivity of 85% and specificity of almost 100% if performed after first week of illness. These are often the first tests ordered for the diagnosis of acute IM. These tests are less useful in younger children less than 2–4 years of age. If these tests are negative but IM is strongly suspected then EBV-specific antibody testing should be done to confirm the diagnosis. Heterophile-negative IM means any patient who remains heterophile-negative for more than 6 weeks after diagnosis of IM.

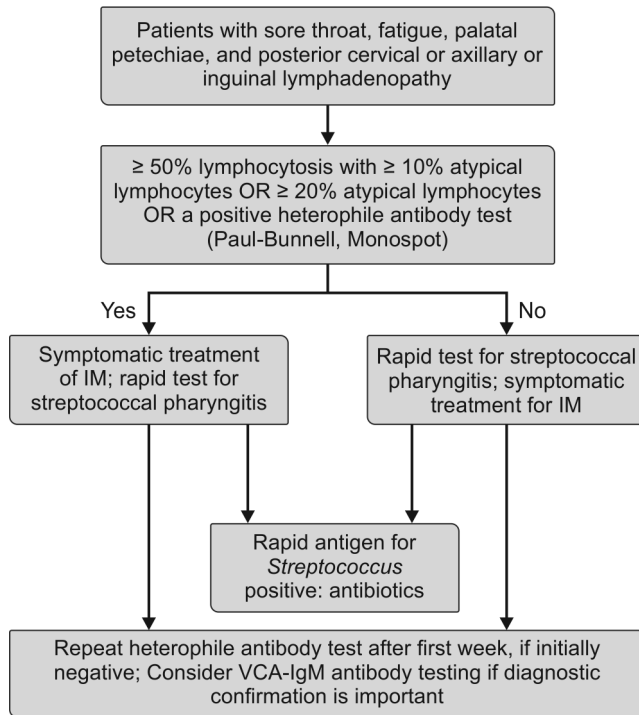

EBV-specific antibodies These tests are indicated for confirmation of either an acute infection (including heterophile negative cases) or a past infection. Viral capsid antigen (VCA), nuclear antigen (EBNA), and early antigen (EA) are the widely used tests. The VCA-IgM and IgG antibody tests are the most useful in confirming the diagnosis of acute infection and differentiating it from previous infection. The VCA-IgM antibody sometimes may be detected up to 3–6 months after acute infection. Presence of rheumatoid factor may result in a false-positive VCA-IgM test. VCA-IgG level rises later in the acute phase, then declines gradually, persisting with variable titer throughout the life. Antibody to EBNA is detectable 6–8 weeks after the onset of symptoms, and has the same significance as VCA-IgG in distinguishing acute from previous infection. Early antigen is present in early phase and is less useful for diagnosis of IM. Serological features of IM are described in **Table 3**.

Diagnostic Approach

There is no consensus or evidence-based guideline available presently for evaluation of a suspected case of IM. A simple diagnostic approach based on the present available evidence may be followed as shown in **Flow chart 2**.

MANAGEMENT

Good supportive care is the mainstay of treatment that includes control of fever and myalgia by paracetamol or non-steroidal anti-inflammatory drugs (NSAIDs), maintenance of adequate hydration, and administration of lozenges or local anesthetic spray (2% xylocaine) or gargling to relieve sore throat/pharyngitis.

Flow chart 2 Algorithm for the management of suspected infectious mononucleosis

Clinical trials suggest that strict bed rest with severe activity limitation may delay the recovery from illness. So, it seems reasonable to advise patients against strict bed rest, and to resume various activities based on the energy levels. Contact sports and strenuous physical activities should be particularly avoided during the initial 2–3 weeks of illness or till splenomegaly is present, in order to avoid splenic rupture.

A systematic review analyzing the data on acyclovir found less oropharyngeal shedding of the virus at the end of treatment. As acyclovir did not provide any significant clinical benefit, it is not recommended for the treatment of IM. One trial tested the combination of acyclovir and prednisolone, but this combination did not reduce the duration of symptoms significantly and hence not recommended in the treatment.

Because of the unpredictable course of illness, oncogenic complications associated with the virus, and the risk of bacterial superinfection, steroid therapy is not generally indicated for an uncomplicated case of IM. Prednisone (1 mg/kg/day, maximum 60 mg/day) for 1 week with subsequent tapering over next 1 week may be used for life-threatening complications like airway obstruction, thrombocytopenia with bleeding, autoimmune hemolytic anemia, and severe central nervous system (CNS) (seizure, meningitis, encephalitis) manifestations.

PROGNOSIS

The prognosis for complete recovery is excellent if no complications ensue during the acute illness. In a large study on the natural history of IM, the patients were followed till 6 months. The results were as follows: fever, sore throat, headache, cough, rash and nausea resolved after 1 month of the onset of symptoms; fatigue, joint soreness and sleepiness resolved more slowly over a period of 6 months. There was also a steady improvement in the functional status requiring almost 2 months for complete functional recovery. There are several rare complications of IM that one should be

Table 4 Potential complications of infectious mononucleosis

Respiratory problems		
Upper airway obstruction		Pneumonia/pneumonitis
Hematological problems		
Hemolytic anemia		Hemophagocytic lymphohistocytosis
Thrombocytopenia		Red cell aplasia
Pancytopenia		Severe granulocytopenia
Neurological abnormalities		
Meningitis		Encephalitis
Guillain-Barré syndrome		Reye syndrome
Cranial nerve palsies		Retrobulbar neuritis
Acute disseminated encephalomyelitis (ADEM)		Ataxia
Alice in wonderland syndrome (metamorphopsia)		Seizure
Cardiovascular		
Myocarditis		Conduction abnormalities
Others		
Hepatitis	Interstitial nephritis	Genital ulcer
Splenic rupture	Pancreatitis	Bacterial superinfection

aware of, and these are mentioned in **Table 4**. Studies have found that, a higher VCA-IgM titer ($>100 \mu\text{mL}$) and female gender are associated with an increased risk of complications.

PREVENTION

As the virus is transmitted through saliva, close contact with saliva may be avoided during the acute phase. There is no role of isolation of the patient and is not recommended. There is no vaccine available against EBV. Clinical trials are undergoing presently to find a suitable vaccine.

IN A NUTSHELL

1. Infectious mononucleosis should be suspected in any patient with sore throat, fatigue, palatal petechiae, lymphadenopathy (posterior cervical or axillary) and splenomegaly.
2. Relative lymphocytosis ($>50\%$ lymphocytes) including 10% atypical lymphocytes or at least 20% atypical lymphocytes or a positive heterophile antibody test favors the diagnosis.
3. When the diagnosis of IM is suspected, a heterophile antibody (monospot) test should be ordered first, and a negative test should be repeated after 1 week for further confirmation.
4. When diagnosis confirmation is important or in heterophile negative cases, VCA-IgM antibody testing is recommended.
5. Infectious mononucleosis like syndrome (IMLS) including toxoplasmosis, streptococcal infection, CMV or other viral infections may show negative heterophile antibody test.
6. Good supportive care is the mainstay of treatment, and includes antipyretics or analgesics, adequate hydration, gargling or lozenges and bed rest.
7. There is no role of steroid or acyclovir in the routine uncomplicated cases of IM, although steroids may be used for life-threatening complications like airway obstruction or bleeding or CNS manifestations.
8. Contact sports or strenuous physical activity should be avoided during the initial 2–4 weeks of illness to avoid splenic rupture.
9. Few symptoms like fatigue, myalgia, joint soreness and sleepiness may persist up to 6 months following resolution of the acute illness.

Chapter 31.13

Enteroviral Infections

Annapurna Sudarsanam

Enteroviruses (EVs) along with rhinoviruses (RVs) are the commonest cause of viral infections in childhood. EVs are implicated in a wide range of human diseases including aseptic meningitis, acute flaccid paralysis (AFP), vesicular and exanthematous skin lesions, myocarditis, pleurodynia, severe generalized disease of the infants and undifferentiated febrile illness. Subclinical infection is by far the most common infliction.

ETIOLOGY

Enteroviruses of human origin include the following species:

- Poliovirus, types 1–3
- Coxsackie A virus, types 1–24 (no type 23)
- Coxsackie B virus, types 1–6
- Echovirus (E), types 1–33 (no type 10, 22, 23 or 28)
- Enterovirus, types 68–71.

Enteroviruses were originally classified by their antigenic and pathogenic properties in humans and mice. Since the 1960s, new EVs have been assigned numbers rather than being classified as coxsackievirus (CV) or echovirus. E-22 and E-23 have been reclassified as parechovirus. A new system of classification based on genetic relatedness divides the EV into types A–D. The virion consists of a 28–30 nm icosahedral capsid shell made of 60 subunits each comprising of four proteins VP1–4 surrounding a single-stranded positive-sense RNA. EVs are relatively resistant to common disinfectants like 70% ethanol, dilute lysol, isopropanol, quaternary ammonium compounds. They are insensitive to lipid solvents like chloroform and ether. Formaldehyde, glutaraldehyde, free residual chlorine, hypochlorite, strong acid and UV light can inactivate them. Although relatively thermostable, most EVs are inactivated at 42°C making it possible to use pasteurization to inactivate them.

EPIDEMIOLOGY

Host Factors

Rate of infection is highest in the first 12 months of life. Most of the enteroviral meningitis occurs in the first 4 months of life and majority of the severe EV71-associated brainstem encephalitis occurs in first 2 years. Male sex has been associated with a greater risk of enteroviral infection in infancy and childhood by almost a factor of two. Factors that increase susceptibility to enteroviral infections include age, male sex, low socioeconomic status, overcrowding and poor hygiene. Vertical transmission of maternal antibodies or through breastmilk is protective for the first 3–6 months. Human leukocyte antigen (HLA)-A33, which is a common phenotype in Asian populations but rare in Caucasians, has been associated with increased susceptibility to EV71 infection. HLA-A33 (class I) and HLA-DR17 (class II) may also contribute to the severity of the disease caused by human enterovirus 71 (HEV71) infection.

Environmental Factors

Enteroviruses are ubiquitous. Whilst they circulate all year round there is a marked increase in seasonal periodicity noted over the summer and fall in the temperate climates. In the warmer areas, higher excretion rates are observed and disease occurs in an endemic pattern.

Transmission

Humans are the only reservoir for the EV. Transmission occurs mainly through close contact with an infected person via fecal-oral route or respiratory droplets. Nonimmune household contacts are at high risk for infection. Secondary attack rates may be as high as 75% within families. Crowded situations like day care centers, school, nurseries, orphanages, summer camps increase risk of quick spread and outbreaks of infections. Vertical transmission from mother to the child during delivery or via breastmilk is also known. Rarely in utero transmission has been reported. Given the hardy nature of the viruses, transmission can also occur via contaminated surfaces/fomites. Transmission via contaminated food and water is possible but rarely reported. Viruses are present in the tears and conjunctival secretions and may contribute to explosive outbreaks of acute hemorrhagic conjunctivitis due to CV-A24 and EV70.

PATHOGENESIS

Following the initial infection either via the respiratory or fecal-oral route, the virion attaches itself to the cytoplasm of the mucosal cells of the oropharynx via cell surface receptors. Following attachment to the cell surface receptor, the viral RNA is released into the cytoplasm. Translation of positive-sense RNA results in the production of a polypeptide which is further cleaved down by the virus-encoded proteinases. The proteins generated enable replication of the viral RNA after which the RNA and proteins are assembled into 30 nm virion particles. The replication process results in the generation of 10^4 – 10^5 virions which are released following cytolysis within 5–10 hours after the initial infection. Mucosal replication and cell-to-cell spread is followed by spread to the local lymphoid tissues such as the tonsils, Peyer's patches and regional lymph nodes. This is followed by a *minor viremia* with spread of the virus to the distant reticuloendothelial tissue including lymph nodes, liver, spleen and bone marrow. The levels of virus are low and transient in this phase. Host immune system especially circulating antibodies directed against the VP1 capsid proteins may limit the further spread of the virus resulting in a subclinical infection. Alternatively the virus further replicates followed by a *secondary viremia* and infection of the target organs which may be the skin, central nervous system (CNS), liver, kidneys, muscles, heart or pancreas. Tissue tropism is determined by the infecting virus serotype.

PATHOLOGY

Local tissue damage results from direct viral cytolytic effects and from the inflammatory response triggered. Meningeal infection is associated with a mononuclear pleocytosis in the cerebrospinal fluid (CSF). Encephalitis involving the white and gray matter, deep gray nuclei, brainstem and cerebellum is associated with perivascular lymphocytic infiltration, parenchymal infiltration with inflammatory cells, gliosis, neuronal phagocytosis and cell necrosis. Severe EV71 encephalitis is associated with involvement of the brainstem, spinal cord gray matter, subthalamic and dentate nuclei. In severe cases, it has been associated with neurogenic pulmonary edema, interstitial pneumonitis and cardiac failure due to sympathetic overactivity. Myocarditis with enteroviral infection is characterized by mixed inflammatory infiltrate. Macrophages predominate in the early stages and contribute to viral clearance. Natural killer cells and T lymphocytes cause necrosis of the infected myocytes. Persistence of viral infection of the myocardium has been linked to dilated cardiomyopathy. Immunocompromised patients, especially those with humoral immunodeficiency, are vulnerable to severe disease and also suffer from chronic EV infections. A role of molecular mimicry and bystander damage,

i.e., upregulation of the nonspecific immune response by the virus has been suggested in explaining some of the pathogenic effects of enteroviral infections including CV-B4 associated diabetes mellitus (DM) and CV associated myocarditis.

Immunity

Enteroviral infection is followed by the development of serotype specific immunoglobulin M (IgM) antibodies. More long-term immunity is provided by IgG and IgA which also provides mucosal immunity. Reinfection with the same serotype may occur but it does not proceed to clinical infection and the duration of viral shedding is also much shorter. However, there is evidence to suggest infection by a different serotype may be enhanced by the presence of heterotypic antibodies.

CLINICAL FEATURES

The incubation period for EV is 3–6 days except for acute hemorrhagic conjunctivitis for which the incubation period is 1–3 days. Viral shedding via the respiratory route from infected children persists for 1–3 weeks while that from the fecal route may persist for 7–11 weeks. Majority of the enteroviral infections are asymptomatic and the most common clinical feature would be an undifferentiated febrile illness. However, the EVs have been associated with a myriad of acute and chronic illnesses. A variety of EV can cause the same disease manifestation or there may be a typical illness pattern associated with a particular serotype. Outbreaks of illnesses may be associated with several circulating serotypes at the same time.

Nonspecific Febrile Illness

This is the most common manifestation of enteroviral illness. The typical symptoms include abrupt onset fever 38.5–40°C (101–104°F) associated with irritability, lethargy, poor feeding, vomiting, diarrhea, rhinorrhea, with or without a rash. EV infection can cause respiratory distress, pneumonia, otitis media, bronchiolitis, croup, parotitis, and pharyngotonsillitis which may be exudative. Genitourinary manifestations such as orchitis and epididymitis are possible. A variety of exanthems may be associated with EV including macular, maculopapular, vesicular, urticarial rashes and papular acrodermatitis. Older children may present with headache and myalgia. Almost all the infants recover in 7 days without sequelae. New infection with a different EV serotype is not uncommon. Enteroviral exanthems typically occur in children less than 10 years. The younger the age the more common it is. Petechial and purpuric rashes have been associated with E-9 and CV-A9 that can be confused with meningococcal disease.

Hand, Foot and Mouth Disease

The hand, foot and mouth disease (HFMD) is a highly contagious viral illness and is one of the classic exanthematous diseases associated with EV that affects predominantly children. Fever and sore throat may be the initial symptoms followed by the appearance of a typical rash that is maculopapular or vesicular on the hands and feet (**Fig. 1**) and oral ulcerations. Oral lesions involve the tongue, buccal mucosa, gingiva, posterior pharynx, palate and lips. Maculopapular-vesicular rash may also be present on the buttocks and groin. The typical illness is short lasting associated with no to mild fever. The vesicles start drying in a week's time. Majority of the HFMD cases are associated with CV-A16 and EV71. Since the year 2000, several large HFMD outbreaks have been reported in many Asian regions such as China, Malaysia and Vietnam. Smaller outbreaks have been reported from parts of India since 2004. The EV71 HFMD tends to be more severe and may be associated with a severe progressive form associated with neurological and cardiopulmonary complications. Other EV serotypes, CV-A4–7,

Figure 1 Hand, foot and mouth disease
Source: Dr Madhumita Banik, Kolkata, India.

CV-A9–10, CV-B1–3, CV-B5, E-4 and E-19, have also been found associated with both sporadic infections and outbreaks of HFMD. CV-A6 in recent outbreaks has been associated with classical HFMD as well as with an atypical perioral or more generalized distribution of rash or a vesiculobullous rash type. Children with eczema may be more affected and *eczema coxsackium* was coined as far back as 1968 for this condition. Postinfectious loss of the nails is reported frequently.

Herpangina

Herpangina is an enanthem associated with EV typically coxsackie A virus and occasionally some coxsackie B serotypes and echoviruses. The illness is characterized by abrupt onset high-grade fever with sore throat, odynophagia, vomiting and headache. The typical lesions present as grayish bumps 1–2 mm in size mainly over the tonsillar pillars, tonsil, posterior pharynx, uvula and soft palate. They ulcerate within a day or two forming shallow ulcers up to 5 mm in size with an erythematous border. The illness is usually self-limiting and clears in about a week. Occasional cases of association with aseptic meningitis have been reported.

Acute Hemorrhagic Conjunctivitis

This was first reported in 1969 from Ghana. Several outbreaks have since been reported from Japan, Singapore, India, the United States of America, China, Cuba, Pakistan, Egypt and Thailand. Epidemiologic studies have implicated CV-A24 and EV70 strains as causative agents. A large epidemic involving over 200,000 people was reported from Brazil in 2006. The illness is characterized by conjunctival congestion, eye pain, blurred vision, excessive tearing, vascular dilatation and chemosis, followed by appearance of subconjunctival hemorrhage. The illness runs a 5- to 7-day course and usually resolves without any sequelae. Superadded bacterial infection may occur. Rarely neurologic complications like aseptic meningitis and AFP have been reported. Older children between 10 years and 14 years tend to be at the highest risk. The disease is highly contagious. Apart from fecal-oral transmissions, direct ocular transmission through contaminated tears can occur.

Other ocular manifestations of enteroviral infections in children include uveitis, optic neuritis, chorioretinitis and unilateral maculopathy. EV uveitis is a new infant eye disease that was first observed in 1980. Three distinct subtypes of human echoviruses, E-19/K, E-11/A and E-11/B, caused five hospital outbreaks in different Siberian cities in 1980–1989, affecting approximately 750 children, predominantly below 1 year of age.

Meningitis and Encephalitis

Enteroviruses are the most common cause of viral CNS infections. All enteroviral genera and almost all serotypes show neurotropism. Aseptic meningitis is the most common CNS infection. Echoviruses and group B CVs account for over 90% of the cases of viral meningitis. Risk of infection seems to be highest in the first year of life. Older children may develop a biphasic illness with an initial prodrome of fever and sore throat followed by abrupt onset of fever and headache. Encephalitis is characterized by alteration of consciousness, neurological weakness and focal seizures. Hemichorea and acute cerebellar ataxia have been reported in infants and toddlers with coxsackie A viral encephalitis. Complications such as febrile seizures, focal seizures, lethargy, coma and movement disorders can occur in 5–10% cases. Viral meningitis can be inferred from CSF analysis. The CSF white cell count can vary from 10 to over 1,000 with early polymorph predominance in the first 2 days of the illness followed by a lymphocytic predominance. Viral cause can be confirmed through viral isolation in cell culture or by polymerase chain reaction (PCR). Subtle impairment of motor function such as motor incoordination, muscle spasm or restriction of passive motion may persist for few weeks after the acute illness but generally the long-term neurocognitive outcome is good. Prominent neurologic complications with EV71 include not only aseptic meningitis with or without encephalitis, but also, more rarely, acute flaccid poliomyelitis-like paralytic disease, opsoclonus-myoclonus syndrome, benign intracranial hypertension and brainstem encephalitis. In 2012, EV71 caused particularly severe disease with brainstem encephalitis-associated cardiopulmonary dysfunction and death in young children in Cambodia. Neuroimaging and electroencephalographic (EEG) changes reflect the extent and severity of the involvement. Although majority make full recovery neurologic sequelae and rare deaths can occur. Factors associated with severe, especially fatal disease, were young age, male gender, high white count, prolonged high fever, high glucose, high C-reactive protein (CRP) and neurological findings.

Acute Flaccid Paralysis

Although poliovirus is the typical EV associated with AFP, several nonpolio EVs have in more recent times been associated with AFP. EV71 has been associated with outbreaks and is the chief viral cause of AFP in postpolio eradication era. The anterior horn cell destruction tends to be less severe than with poliovirus with a better recovery rate. EV70 has also been associated with AFP. It can specifically be associated with cases of bulbar palsy. A recent study from Kerala and Karnataka based on data collected from the Polio Surveillance Program suggested a high nonpolio EV positivity rate amongst AFP cases with a high genotype diversity among the isolates. Nonpolio EV positive AFP cases were significantly higher in children aged less than 2 years; with residual paralysis; in summer months; and in regions with relatively hot climate. A newly defined serotype EV94 was isolated from cases of AFP in Congo. EV-B106 and EV-B93 have also been isolated from AFP cases in China, Pakistan and Bolivia.

Pleurodynia or Bornholm Disease and Myositis

Pleurodynia or Bornholm disease is an acute febrile illness characterized by myositis of the intercostal and abdominal muscles presenting as severe sharp, localized spasmodic chest and abdominal pain. Coxsackie B viruses, especially CV-B3 and CV-B5, have been most commonly implicated. The severity of pain can often alarm patients into seeking urgent medical advice. Severe chest pain worsened with respiratory effort may result in splinting of chest and tachypnea. Cough is not prominent. The initial presentation may include flu-like symptoms, sore throat and headache. The lung fields are clear on auscultation. Localized

muscle tenderness and swelling and a pleuritic rub may be the only clinical findings. The presentation may mimic pneumonia or pre-eruptive phase of herpes zoster. Whilst it typically runs a benign course which resolves in 4–6 days rare cases with optic neuritis, cardiomyopathy, myopericarditis and meningitis have been reported. It tends to affect the older children and adolescent most commonly. Periodic outbreaks with high rates of transmission occur. Analgesics and rest are the standard treatment strategies. Local infiltration of intercostal nerves with xylocaine has also been reported to be effective.

Enteroviruses have been implicated in acute and chronic myositis. The acute illness may present with acute onset fever, myalgia, and elevated muscle enzymes with or without myoglobinuria. Chronic involvement may present as a subacute or chronic progressive weakness and may present with characteristic skin involvement as dermatomyositis.

Cardiac Involvement

Enteroviruses are the most common virus group associated with myocarditis. The group B CV especially the CV-B3 is the most commonly isolated virus. Clinical presentation may be after an initial febrile flu-like illness followed by cardiac symptoms in the form of chest pain, dyspnea and malaise. A pericardial friction rub may be audible. A gallop rhythm may be present with heart failure. The electrocardiogram (ECG) may show nonspecific ST segment and T wave changes. Various types of arrhythmias and conduction blocks may occur. Creatinine kinase and cardiac troponin may be elevated. Chest X-ray may show an increased cardiothoracic ratio and evidence of heart failure. Magnetic resonance imaging (MRI) and echocardiogram may be useful in assessing the severity and extent of cardiac involvement. The prognosis is better in children than adults with a case fatality rate of ~15%. Up to 10% may go on to develop persistent infection or residual myocyte damage leading to a dilated cardiomyopathy. The persistent viral infection may trigger an immune response that can foster the disease. Symptomatic and supportive management with rest, analgesia, management of arrhythmias and heart failure is the main stay of management. Pleconaril, the experimental antiviral drug has been used in small number of patients with some benefit. Use of intravenous immunoglobulin (IVIG) and other immunosuppressive therapy has not shown to produce a consistent benefit. Milrinone has been useful in severe EV71-associated cardiopulmonary failure. For those with dilated cardiomyopathy and chronic congestive heart failure, cardiac transplantation may be needed.

Neonatal Infection

Enterovirus infections are common in the neonatal period, and most cases are either asymptomatic or minimally symptomatic and without long-term sequelae. In a minority of cases, characterized by hepatic or cardiac involvement, EV infection may be severe or fatal. Immaturity of the innate immune system which may fail to limit the initial enteroviral replication makes neonates vulnerable. The severity of the infection is also dependent on the presence or absence of passively transferred maternal type specific immunity. The dominant mode of transmission of serious neonatal infection is likely at the time of delivery through contact with maternal blood, fecal material, or vaginal or cervical secretions. Transplacental infection can occur in utero. Nosocomial infections also occur in nurseries if adequate precautions are not taken. Initial presentation may be as a febrile, irritable or lethargic neonate with poor feeding. Those with severe disease may progress to develop myocarditis, encephalitis or fulminant hepatitis. Prematurity, maternal illness, early age of onset of illness (younger than 7 days of age), higher WBC count ($15 \times 10^9/L$ or greater) and low hemoglobin (10.7 g/dL or lower) have been associated with severe disease.

Neonatal myocarditis is most commonly caused by coxsackie B serotype 1–5 and less commonly by E-11. After the initial prodrome, neonates rapidly progress to overt heart failure. Seizures, bulging fontanel and CSF pleocytosis may occur with encephalitis. Cyanosis and hypotension are poor prognostic signs. Mortality rates may be 30–50%.

Fulminant neonatal hepatitis may occur with E-11 infection and can present as an enteroviral sepsis syndrome with progressive jaundice, hypotension and bleeding leading to multiple organ failure. The illness carries a high mortality despite maximal intensive care. Extensive hemorrhage into the cerebral ventricles, pericardium and interstitium of various solid organs may be found. Apart from supportive therapy, blood products, IVIG and pleconaril have been used on an anecdotal basis with some benefit.

Diabetes Mellitus

The role of enteroviral infections in type 1 DM has been investigated in epidemiological and animal studies. There is evidence to suggest an increased risk for beta-cell autoimmunity and hence type 1 DM after EV infection especially CV-B1 infection. The recent discovery of *IFIH1* gene, which is an innate immune system receptor for EV as a risk gene for type 1 DM further lends evidence to this potential link. Infection with CV-B6 and CV-B3 has been associated with a reduced risk. The association is interesting and offers potential for prevention of diabetes through development of vaccines against specific enteroviral types.

DIAGNOSIS

Most enteroviral infections go undiagnosed or a fairly certain presumptive diagnosis is established based on the characteristic clinical presentation in the context of a seasonal outbreak. Specific diagnostic tests may be useful in epidemiological studies, infection surveillance or in a very sick or unwell child to direct appropriate treatment or in postmortem samples from cases of myocarditis, neonatal infections and encephalitis. Three main diagnostic methods are the *viral cell cultures* which is the gold standard but time consuming and less sensitive, nucleic acid assays based on *reverse transcriptase PCR (RT-PCR)* or *serology*.

Viral shedding in stools may persist for 7–11 weeks and contribute to a false-positive test.

A cloned EV complementary DNA prepared from the highly conserved 5' region of the EV genome can be used for rapid and sensitive group-specific diagnosis of EV infections. The RT-PCR can detect the virus fairly quickly within 2–4 hours from small amounts of biological specimens. Serological diagnosis relies on demonstration of a fourfold rise in the titers of specific neutralizing antibodies between acute and convalescent phases. Serological assays using microneutralization techniques or complement fixation, enzyme immunoassays or indirect fluorescent antibody assays are available. Serological tests are less useful than RT-PCR or viral cultures.

VIRUS PERSISTENCE

Persistent EV infection has been demonstrated in immunodeficient and less commonly in the immunocompetent host. Patients with immunodeficiency, especially X-linked agammaglobulinemia or hypogammaglobulinemia, can develop a chronic nonpolio EV-induced aseptic meningitis or meningoencephalitis. These patients may have an associated dermatomyositis type syndrome with inflammation of multiple organs. Persistence of EV or the EV genome has been reported in immunocompetent humans and animals with varied diseases including chronic dilated cardiomyopathy, inflammatory muscle disease (myositis) and diabetes. In addition, EVs including poliovirus have been implicated in the cause of postpolio syndrome and amyotrophic lateral sclerosis.

TREATMENT

In the absence of availability of specific licensed antienteroviral drug therapy, the management of most of the enteroviral illness is symptomatic and supportive. In addition, a great majority of the infections are self-limited and do not require specific therapy. Exceptions to this situation are severe illnesses including neonatal infections, encephalitis, acute myocarditis and infections in the immunocompromised. Use of IVIG has been trialled on the presumptive basis of presence of specific neutralizing antibodies and also for nonspecific anti-inflammatory effects. Retrospective reviews suggest benefit when given early in severe diseases such as EV71-associated encephalitis. Studies have shown substantial reduction in concentrations of some proinflammatory cytokines after IVIG in EV71 encephalitis with autonomic dysfunction but not in less severe cases. IVIG has therefore become more routinely used in the treatment of severe EV71 disease and has been incorporated into the national guidelines in Taiwan. Pooled immunoglobulin delivered intravenously or via a shunt into the spinal fluid has also been used in patients who are agammaglobulinemic with chronic encephalitis and meningitis associated with nonpolio EV. Use of corticosteroids and immunosuppressive drugs like cyclosporine has been reported in the literature with uncertain effect.

Antiviral Therapy

Potential antiviral agents target various steps in the viral life cycle including attachment, entry, uncoating, translation, polyprotein processing, virus-induced formation of membranous RNA replication complexes and RNA-dependent RNA polymerase are currently under evaluation. Three candidate compounds are currently in development: (1) pleconaril (active against many EV), (2) V-073 (antipoliavirus) and (3) BTA-798 (active against many RVs and EV). Pleconaril remains the most promising drug which inhibits replication of most EV serotypes. It is a novel agent which integrates with the picornavirus capsid and prevents the virus from attaching to the cellular receptors and uncoating to release the viral RNA. Trials in patients with enteroviral meningitis have shown reduction in duration and severity of headaches and other symptoms with shorter period of viral shedding. Trials in B-cell deficient people with persistent enteroviral infections and in those with potentially fatal illness including neonates, and those with acute myocarditis have suggested substantial benefits. Mutant viruses resistant to the drug can arise. Ribavirin and lactoferrin have also shown potential benefits in *in vitro* and *in vivo* studies. Herbal products like geraniin have also shown similar potential.

PREVENTION

Good simple hygiene measures are of primary importance in preventing spread of EVs especially during outbreaks. These measures involve regular hand washing with soap and water, careful disposal of nappies of infected children, disinfecting contaminated surfaces, keeping affected children away from day care centers, schools and nurseries. Pregnant women should avoid contact with people suspected to have enteroviral illness. Isolation is warranted in hospital and neonatal unit settings.

Prophylactic administration of immunoglobulins may be beneficial to neonates in case of maternal infection. Maintenance antibody replacement with high-dose IVIG for patients with hypogammaglobulinemia has reduced the incidence of chronic EV meningoencephalitis.

A Vero cell-based inactivated human EV71 vaccine has been developed with the use of EV71 strain H07 (subgenotype C4) as the seed virus. The vaccine has completed phase III trial successfully providing effective protection against EV71-associated (but not

to other serotype associated) HFMD or herpangina in infants and young children without significant adverse reactions. The vaccine was trialled in children aged 6–35 months and as two 0.5 mL intramuscular injections 28 days apart. Long-term surveillance of the study participants is being performed to evaluate the longevity of serologic responses and vaccine protection and the need for booster injections. Vaccines for other virulent serotypes are also currently being researched.

IN A NUTSHELL

1. Enteroviruses are ubiquitous. Infections occur with seasonal periodicity in the summer and fall in temperate regions.
2. Majority of the infections are asymptomatic or cause self-limited minor illness.
3. Major outbreaks of illness occur with regular periodicity and may be associated with severe disease and fatality especially in the very young and immunocompromised.
4. Treatment is mainly supportive and symptomatic although IVIG and antiviral agents like pleconaril have been used anecdotally with some benefit in severe illness.

Chapter 31.14

Herpes Simplex Infections

Niranjan Mohanty, Pradeep S

The family herpesviridae contain three subfamilies: (1) alphaherpesvirinae, (2) betaherpesvirinae and (3) gammaherpesvirinae. Herpes simplex virus (HSV) belongs to alphaherpesvirinae. Characteristics of the alphavirinae are short reproductive cycle, and efficient destruction of infected cells with release of viral progeny, rapid spread in culture, and latency in sensory ganglia. HSV-1 and HSV-2 belong to subfamily of alphaherpesvirinae. Eight herpesviruses are pathogenic to human, of which HSV-1 and HSV-2 are the major contributors. The word *herpes* means *to creep* in Greek. The earliest description of herpes as *fever blisters* was recorded by Hippocrates and Herodotus. In 17th century, Astruc described genital herpes lesion and in 1912, Gruter cultured HSV virus on rabbit cornea. Approximately one-third of children from lower socioeconomic population and about 20% from middle class have serologic evidence of HSV infection by 5 years of age. Direct person-to-person contact occurring in crowded living conditions partially accounts for these differences.

ETIOLOGY

The herpes viral particle has more than 30 structural proteins, icosahedral nucleocapsid with 162 capsomers and 100 nm in diameter. The viral particle is surrounded by an envelope, acquired via budding through inner lamella of nuclear envelope, multiple surface projections embedded in envelope. HSV-1 primary infection usually occurs in infancy or childhood, whereas primary infection with HSV-2 occurs after onset of sexual activity. Humans are the only known reservoir. Two types of HSV can be distinguished by restriction enzyme analysis of DNA, antigenic structure by Western blotting, and certain antigenic determinants. The viral glycoproteins are the major target for humoral immunity whereas other nonstructural proteins are important targets for cellular immunity. Several viral surface glycoproteins appear to be determinants of virulence. The glycoproteins like gB and gC mediate cellular attachment, gD is required for viral entry, gE for efficient expression of late genes and gI is a potent Fc receptor.

PATHOGENESIS

Infection of susceptible host occurs when the virus enters through the mucosa (oral mucosa, conjunctiva, genital mucosa) or break in keratinized epithelium. After entering the host virus replicates locally and enters nerve endings and replicates in sensory nerve ganglions. Then it moves through the neural arches which cause the characteristic herpetic lesion. Pathology of skin lesions shows sequential changes of balloon degeneration of infected cells, with condensation of nuclear chromatin, degeneration of cell nuclei and plasma membrane and formation of multinucleated giant cells. Mucosal membrane lesions are more prone for ulceration than skin lesions as thin layer of mucosal epithelium ruptures easily. When host is unable to control the viral replication (neonate or immunocompromised host), viremia occurs eventually leading to multiorgan involvement (**Flow chart 1**).

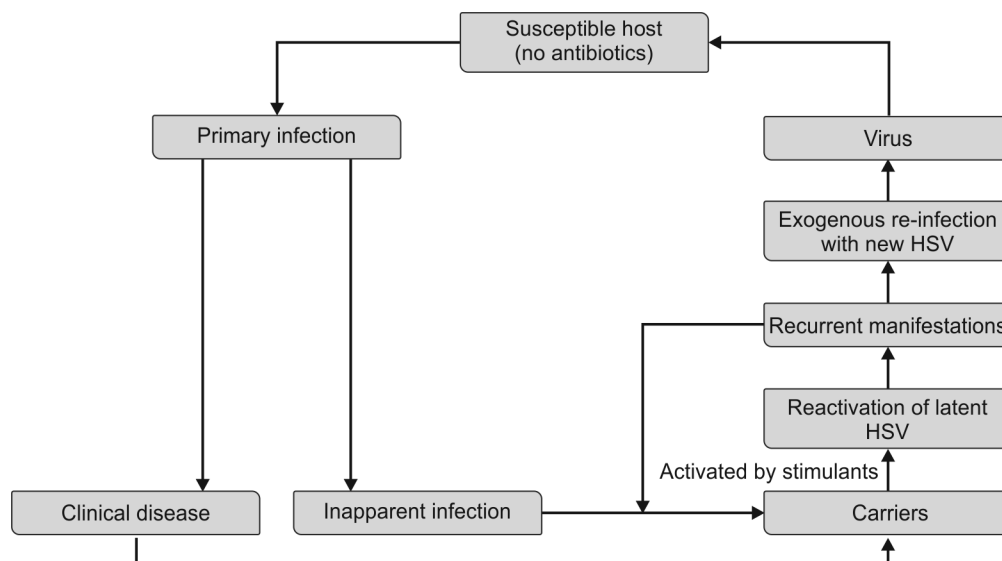

All herpesviruses have characteristic property of becoming latent after primary infection. Reactivation of HSV is regulated by the host immune factors, expression of cellular proteins in neuron and expression of HSV protein. A number of stimuli causing reactivation include manipulation of nerve roots, direct trauma to ganglia or skin/mucosa innervated by peripheral nerve, exposure to UV light, stress, hormonal changes, immunosuppressive agents and intercurrent infections. Recurrences are more common with HSV-1 and HSV-2, causing orolabial infections and genital infections, respectively. HSV infection can manifest as:

- **Primary infection** occurs in individuals who have not been previously infected by HSV-1 or HSV-2. The infections are severe due to lack of seropositivity.
- **Nonprimary infection** occurs in patients who have been exposed previously to either HSV-1 or HSV-2. The infections are not severe due to some level of cross protection.
- **Recurrent infection** During primary or non-primary infection, HSV establishes latent infection in regional sensory ganglion neurons. Usually they are asymptomatic.

CLINICAL FEATURES

Clinical manifestations depend on the type of infection (primary / nonprimary or recurrent), type of virus, port of entry, gestational age of neonate and maternal immunity. The typical lesions in primary infection manifest as small to large vesicles surrounded by an erythematous base, which eventually develops into ulcers and usually heals without scarring.

Flow chart 1 Host parasite interrelationship of herpes simplex virus (HSV)

Orolabial Infection

Primary infection classically presents at the age of 6 months to 5 years with extensive orolabial painful lesions (**Fig. 1**), high fever, irritability, drooling of saliva, refusal to feed and tender submandibular lymphadenopathy. Lesions heal without scarring in 6–10 days. Dehydration is the most common indication for hospitalization.

Reactivation lesions are usually asymptomatic, but the most commonly affected sites being outer edge of vermillion border of the lip and ophthalmic division of trigeminal nerve.

Cutaneous Herpes

Cutaneous herpes infections caused by direct contact and lesions develop at the port of entry. The manifestations range from severe pain to burning and itching mainly before the eruption of lesion. Herpetic whitlow refers to HSV infection of fingers and toes. Surgical intervention is contraindicated. HSV is most commonly recognized precipitating factor for recurrent erythema multiforme.

Genital Herpes (due to HSV-2)

Primary infection Nonspecific symptoms develop within 7 days of incubation. Lesions are distributed over the shaft of the penis in males and over labia, mons pubis, cervix and vaginal mucosa in females. Tender lymphadenopathy appears in 2nd and 3rd week of infection.

Nonprimary first episode Less severe lesions with more rapid healing and less severe complications.

Reactivation Usually asymptomatic, the carriers keep shedding the virus for long time.

Ocular Herpes

Infections occur through direct contact or peripartur route. Follicular conjunctivitis with pain, photophobia and tearing is followed by chemosis, periorbital edema and preauricular tender lymphadenopathy. Pathognomonic dendritic ulcers are the most common ocular manifestations of recurrent herpes.

CNS Herpes

Herpes simplex virus is the most common cause of severe, sporadic, fatal encephalitis world over. Encephalitis can be due to primary infection or more commonly due to reactivation. Beyond

neonatal period, HSV encephalitis is virtually caused by HSV-1. There occurs an acute necrotizing inflammation of temporal and frontal lobe and limbic system with hemorrhagic discharge into cerebrospinal fluid (CSF). HSV is the leading cause of recurrent aseptic meningitis (Mollaret's meningitis). CSF findings include RBC ($> 1,000/\text{mm}^3$), lymphoid pleocytosis ($> 1,000/\text{mm}^3$) and protein concentration which increase after the first week up to 500–1,200 mg/dL. Electroencephalogram (EEG) shows focal spike and slow wave abnormality with characteristic findings of paroxysmal lateralizing epileptiform discharges (PLEDs). The disease has very poor prognosis with subsequent death occurring in 75% of cases.

Herpes in Immunocompromised Hosts

In immunocompromised hosts, HSV infection is a frequent source of morbidity and the risk of severity parallels the extent of compromise in cellular immune response. Mucocutaneous infections (mucositis and esophagitis) are most common and may cause ulcerations deep into the tissue and necrosis. The healing takes an average of 6 weeks. Other infections include tracheobronchitis, pneumonitis and hepatitis. Viremia can lead to disseminated sepsis, shock and disseminated intravascular coagulation (DIC).

Neonatal Herpes

The estimated prevalence of neonatal herpes is 1 in 3,000–5,000 live births. Around 70–80% neonatal HSV infections are due to HSV-2. The infection occurs more commonly in infants born to mother with recent infection rather than due to recurrent genital herpes. HSV infection is acquired during in utero, peripartum or postpartum, often during delivery. Risk of transmission is high with mother having primary infection or with intrapartum interventions and baby with low gestational age.

Patterns of Neonatal Herpes

Neonatal HSV infection manifests in three ways with almost equal proportions having considerable clinical overlap: (1) *Skin, eye and mouth* (SEM) form is never asymptomatic. They present with skin lesions from birth or typically manifests within 2 weeks of life (**Fig. 2**). Usually the skin lesions appear at the site of trauma as vesicles. Any vesicle on a neonate HSV infection should be considered. The common ocular lesion is keratoconjunctivitis which can progress to chorioretinitis, cataract and retinal

Figure 2 A 10-month-old native American infant presented with herpes simplex (HSV-2) skin lesions on her face, torso, arm and leg
Source: JD Millar, Public Health Image Library (PHIL), CDC, USA.

detachment despite therapy. Outcome of SEM is excellent if treated at early stage. (2) *Central nervous system (CNS) infection* with or without skin lesions can present as seizures (usually focal and difficult to control), lethargy and irritability with onset around 14–21 days of life. (3) *Disseminated form* presents as shock, hepatomegaly, jaundice, bleeding and respiratory distress within 5–11 days of life. Nearly 70% of cases demonstrate skin lesion during the illness which are often absent at the onset of symptoms.

DIFFERENTIAL DIAGNOSIS

Orolabial infections Viral or bacterial pharyngitis, herpangina, acute membranous tonsillitis, thrush.

Cutaneous infections Eczema of secondary bacterial infection and cellulitis, varicella, eczema vaccinatum.

Genital infections Chlamydial infection, gonorrheal and monilial vulvovaginitis, impetigo, ammoniacal dermatitis with secondary infection.

Ocular infections Any conditions causing conjunctivitis and/or corneal ulcer.

CNS infections Viral meningoencephalitis, cerebral malaria, meningitis, vascular diseases, brain abscess.

Neonatal disseminated form Neonatal sepsis, enteroviral infection, pneumonia, meningitis.

DIAGNOSIS

Cytopathological effects of HSV and isolation on viral culture are the gold standard for diagnosing herpes infection. Fluorescent antibody staining and enzyme immune assay are used for culture confirmation. Isolation of virus or viral DNA by polymerase

chain reaction (PCR) is diagnostic method of choice. Histological examination and viral culture of brain tissue specimen are the most definitive method of confirming the diagnosis of encephalitis. Immunoglobulin M (IgM) antibody estimation is unreliable, but IgG estimation in acute and convalescent serum showing fourfold rise is significant. Presence of type specific antibody to HSV-2 indicates anogenital infection. Polymorphonuclear leukocytosis occurs in mucocutaneous infection and in disseminated infection, thrombocytopenia, abnormal coagulating profile and raised liver enzymes are documented. Bedside investigation like Tzanck smear can be used to demonstrate the multinucleate giant cell.

TREATMENT

Treatment of herpes simplex infections is shown in **Tables 1** and **2**.

PREVENTION

Horizontal transmission is prevented by isolating the individual till the viral shedding has stopped. Vertical transmission can be prevented by treating the mother during pregnancy, delivery by cesarean within 4–6 hours of rupture of membranes. There are no clear guidelines to start of prophylactic acyclovir in neonates.

PROGNOSIS

Most of the herpes infections are self-limiting, recurrent orofacial herpes can lead to facial scarring. Life-threatening complications can occur in neonates and immunocompromised children causing mortality. Mortality without treatment can go up to 90% in disseminated form and 50% due to encephalitic form. Severe morbid states like postencephalitis sequel, corneal scarring and blindness (neonatal herpes: SEM form) are serious concern for parents and caregivers.

Table 1 Choice of antiviral drug in herpes simplex infections

Clinical syndrome of HSV infection	Agent of choice	Alternative agent
Neonatal herpes	Acyclovir (IV)	
HSV encephalitis	Acyclovir (IV)	
HSV gingivostomatitis	Acyclovir (PO)	Acyclovir (IV)
1st episode genital infection	Acyclovir (PO)	Valacyclovir, famciclovir Acyclovir (IV) (severe disease)
Recurrent genital herpes	Acyclovir (PO)	Valacyclovir Famciclovir
Suppression of genital herpes	Acyclovir (PO)	Valacyclovir Famciclovir
Whitlow	Acyclovir (PO)	
Eczema herpeticum	Acyclovir (PO)	Acyclovir (IV) (severe disease)
Mucocutaneous infection in immunocompromised host (mild)	Acyclovir (IV)	Acyclovir (PO) (if outpatient therapy acceptable)
Mucocutaneous infection in immunocompromised host (moderate to severe)	Acyclovir (IV)	
Prophylaxis in bone marrow transplant recipients	Acyclovir (IV)	Valacyclovir, famciclovir
Acyclovir-resistant HSV	Foscarnet	Cidofovir
Keratitis or keratoconjunctivitis	Trifluridine	Vidarabine

Note: Valacyclovir, a prodrug of acyclovir, and famciclovir, a prodrug of penciclovir.

Table 2 Dose and duration of treatment of herpes simplex infections

Type of infection	drug	Dose	Duration	Comments
Gingivostomatitis	Acyclovir	15 mg/kg/dose (max 1 g/day) oral	5/day x 7 days	If started within 72 hours, severity reduces
Herpes labialis	Acyclovir	200–400 mg/dose oral	5/day x 5 days	Severe infection in burn cases, acyclovir IV 10–20 mg/kg 8 hourly
Frequent and severe recurrence	Acyclovir	200–400 mg/dose oral	2/day, long-term daily usage	
	Valacyclovir	500 mg/dose oral	Once daily, long-term daily usage	
Herpes gladiatorum	Acyclovir	200 mg/dose oral	5/day x 7–10 days	
Genital herpes	Acyclovir (children)	10–20 mg/kg/dose oral	4/day x 7–10 days	Oral is as efficacious as IV therapy. To start within 6 days of onset, to reduce severity, shortens the duration of illness and viral shedding
Adolescents	Acyclovir	400 mg oral	3/day x 7–10 days	
	Famciclovir	750 mg oral	3/day x 7–10 days	
	Valacyclovir	1,000 mg oral	2/day x 7–10 days	
Recurrent infections	Acyclovir	800 mg oral	3/day x 2 days	Based on severity and frequency, psychological impact and transmission to partner
Episodic therapy	Famciclovir	500 mg oral	2/day x 3 days	
	Valacyclovir	100 mg oral	2 times for 1 day	
Long-term therapy	Acyclovir	400 mg oral	2/day for 1 year	For patients with frequent genital HSV, to prevent outbreak, improves quality of life, decreases the risk of sexual transmission
	Famciclovir	250 mg oral	2/day	
	Valacyclovir	500–1,000 mg oral	4/day	
CNS infections (other than neonates)	Acyclovir	10–20 mg/kg/dose IV	3/day x 14–21 days	Other treatment raised ICT, respiratory compromise and seizures
Immunocompromised persons	Acyclovir	5–10 mg/kg/dose IV Severe mucocutaneous, disseminated HSV	3/day, until the resolution of infection is evident	Less severe infections treated with oral acyclovir, famciclovir, valacyclovir
Neonatal herpes	Acyclovir	10–20 mg/kg/dose IV	3/day x 14 for SEM form and 21 days for CNS or disseminated form	

Note: Acyclovir-resistant cases treated with high dose of acyclovir infusion at the rate of 1.5–2 mg/kg/h or IV foscarnet or IV cidofovir.

IN A NUTSHELL

1. Of eight herpesviruses pathogenic to human, HSV-1 and HSV-2 are more prevalent, mostly in children under 5 years.
2. Herpes simplex virus is a DNA virus with short reproductive cycle and latency in the sensory ganglion.
3. Herpes simplex virus infection could be primary, nonprimary and recurrent. Various stimuli can reactivate this infection.
4. Primary infection often leads to serious manifestations, while nonprimary and recurrent infection remain asymptomatic.
5. HSV-1 and HSV-2 predominantly cause orolabial and genital lesions respectively.
6. Neonates and immunocompromised hosts experience more severe illness.
7. Isolation of virus or viral DNA is the diagnostic method of choice.
8. Acyclovir is the drug of choice in appropriate route, dosage and duration.

Chapter 31.15

Influenza

Sonal Kansra, Alison Scott

Globally, diseases caused by influenza viruses result in significant morbidity and utilization of health care services. The potential for rapid spread across political and geographic borders makes this an important public health priority. During epidemics, the highest rates of influenza infection occur in preschool children. Children are also the main disseminators of influenza viruses in the community. Children with underlying chronic conditions are especially vulnerable and likely to need hospitalization. Symptoms are nonspecific, the diagnosis largely clinical and treatment is mainly supportive.

EPIDEMIOLOGY

Influenza viruses have a global distribution. In temperate climates, seasonal epidemics occur mainly during winter while in tropical regions, influenza may occur throughout the year, causing outbreaks more irregularly. Data from the WHO Global Influenza Surveillance Network in India shows a trend of influenza peaks in the month of June to September which is related with the monsoon across major parts of the country. The incidence of influenza illness as well as influenza-associated acute lower respiratory tract infection (LRI) is three times higher in developing countries as compared to the industrialized countries. Under-5 children have the highest rates of influenza infection. A recent epidemiological study estimated incidence of influenza episodes to be 154/1,000/year in under-5 children in developing countries. The rate of influenza-associated acute LRI and influenza-related severe LRI were estimated at 35 and 2/1,000/year in this age group, respectively. The same study calculated the incidence of influenza-related severe acute LRI to be 1/1,000/year giving a population estimate of 256,000 new episodes per year in 2008.

ETIOPATHOGENESIS

Influenza viruses (**Fig. 1**) are RNA viruses belonging to the Orthomyxovirus family. These are of three types: (1) A, (2) B and (3) C. Type A infects humans and other species (waterfowl is thought to be the natural reservoir of influenza) whereas B infects mainly humans. The type A is further subtyped based on surface antigens—hemagglutinin (HA or H) and neuraminidase (NA or N). Types A and B are responsible for most clinical cases. Cases of influenza A occur with seasonal predilection in the cold countries whereas influenza B epidemics usually occur every few years. Influenza viruses are constantly evolving and change in two different ways—(1) antigenic drift and (2) antigenic shift.

Antigenic drift Small, gradual changes in antibody-binding sites (HA and NA) of a virus that may make it resistant to antibodies formed against earlier strains. This type of rearrangement is seen in both type A and type B viruses.

Antigenic shift An abrupt major change that produces a novel influenza A virus subtype that had not previously circulated. Antigenic shift is largely a characteristic of influenza A virus and may lead to epidemics or even pandemics because immunity from the previous virus may not protect completely against the new subtype, meaning the population may have little or no immunity.

Over the last 100 years, there have been five influenza pandemics due to emergence of novel viruses. Most recently a novel H1N1 human-swine-avian reassortant virus in 2009 in North America started a new pandemic which quickly spread globally.

Figure 1 Influenza virus. A three-dimensional (3D) graphical representation of a generic influenza virion's ultrastructure, and is not specific to a seasonal, avian or 2009 H1N1 virus. In this particular view, a portion of the virion's protein coat or *capsid* has been cut away, revealing its inner nucleic acid core proteins. Note the key to the right identifying the virion's protein constituents

Source: Public Health Image Library (PHIL), CDC, USA. Illustrator: Dan Higgins.

CLINICAL FEATURES

Incubation period of influenza is 1–4 days. The child may remain infective for 10 or more days after illness onset. The amount of virus shed is thought to decrease rapidly after 3–5 days. Severely immunocompromised persons shed virus for weeks to months. The spread is usually via large particle droplets (aerosols) but can also be spread via surface contact. Transmission requires close contact as droplets do not remain suspended in air for a long time and travel only a short distance (< 1 m) in the air. Viruses attach to sialic acid containing receptors on the cell surface of respiratory mucosa.

About 30–50% of influenza may be asymptomatic; however, this depends on the characteristics of the influenza virus strain. Clinically influenza is characterized by an acute onset of fever, chills, myalgia, headache, malaise and fatigue. Dry cough, sore throat and nasal congestion may be present. The symptoms are fairly unpleasant but self-limiting. Uncomplicated influenza illness typically resolves after 3–7 days for the majority of persons, although cough and malaise can persist for greater than 2 weeks. Younger children are less likely to report typical influenza symptoms of cough and malaise. They more frequently present with signs and symptoms of croup, bronchiolitis or sepsis (with high temperatures).

In the most recent pandemic of influenza, a large proportion of patients also had gastrointestinal symptoms. Neurological symptoms: encephalopathy, transverse myelitis and Reye syndrome have been uncommonly reported. Cardiac involvement from myocarditis and pericarditis is also described. Although primary influenza pneumonia is a rare complication that may occur at any age and carries a high case fatality rate, it was seen more frequently during the 2009 pandemic and the following influenza season. Secondary bacterial infection, especially with *Staphylococcus aureus* or *Streptococcus pneumoniae*, is a significant concern. This may lead to acute otitis media (almost 40% of children under-3) or bacterial pneumonia especially in young children. Sinusitis and tracheitis may be seen. Risk of serious illness from infection is highest in children less than 6 months of age and children with

pre-existing conditions such as cardiac, neurological disease or immunodeficiency. Children with asthma have a higher rate of hospitalization with influenza.

DIAGNOSIS

Diagnosis remains largely clinical. Symptoms are nonspecific and overlap with other illnesses. Viral cultures, polymerase chain reaction (PCR) and antigen detection usually in nasal or throat swabs can be used to aid clinical diagnosis although the latter two methods cannot distinguish recent from current infection.

TREATMENT

The mainstay of treatment for influenza has been largely symptomatic until recently. Antipyretics, analgesia and adequate oral fluids are recommended but will not reduce the duration of the illness. The pandemic of H1N1 in 2009 brought the use of antiviral agents into public awareness and governments have spent significant amounts of health care budgets stockpiling these agents. The most commonly used agent is oseltamivir (Tamiflu) which is a NA inhibitor, reducing the virus' ability to break through cell walls and infect other cells and replicate.

Previous policies regarding the use of antiviral agents were developed based on studies, which were manufacturer led, demonstrating benefit with oseltamivir to reduce complications and transmission from influenza. A recent Cochrane review (2014) assessed the risk of publication bias by obtaining all relevant full clinical study reports relating to studies in oseltamivir and found that the use of the drug in children reduced symptom duration (but not in asthmatic children); did not affect rates of hospital admission; did not affect incidence of pneumonia; and reduced symptomatic influenza when used prophylactically. The reviewers express significant concerns regarding the likely mode of action, the size of the effects and the incidence of side effects including nausea, vomiting, headaches and renal and psychiatric syndromes. Guidance on the use of oseltamivir may change in response to these findings and readers are advised to review the most current guidelines.

PREVENTION

Preventing Spread

The most important way to stop flu spreading is good respiratory and hand hygiene. Regular washing of hands and cleansing of work surfaces is important. The most benefit from preventing respiratory virus spread from hygienic measures is in younger children. This is however quite difficult to achieve in children due to their frequent and extensive social contact and long duration of viral shedding. The use of isolation and physical barriers in the form of masks, gowns and gloves, may contain influenza epidemics, or the presence of disease on hospital wards. Global measures, such as screening at entry ports, have not been scrutinized closely but are thought to lead to a nonsignificant marginal delay in spread.

Vaccines

The World Health Organization (WHO) believes that vaccination is the principle measure for preventing influenza and reducing its impact. Influenza vaccination has existed since the 1960s and the WHO has produced guidance regarding vaccine composition since 1973. The WHO recommends vaccination strains of influenza following review of epidemiological data. Seasonal influenza vaccines are usually trivalent, and contain a mixture of the strains predicted to be present in the coming influenza season. This is usually two influenza A strains and one of influenza B. Monovalent vaccines have been developed for pandemic strains. Quadrivalent vaccine with a second influenza B virus in addition to the viruses in the conventional trivalent vaccines has been made available since 2013.

The vaccine is produced through a process known as reassortment. This is the method of combining a strain with the predicted combination of HA and NA antigens (strain 1) with a harmless strain that will grow well in an egg (strain 2). Following injection into a fertilized chicken egg, multiple genetic combinations are created and analyzed, leading to the selection of the strain with the combination of appropriate antigens and the ability to efficiently grow in eggs for development. Influenza vaccination can be both inactivated and injected and attenuated which is delivered nasally.

The WHO recommends vaccination in the following groups: nursing home residents; those with chronic medical conditions; the elderly and others, including health care workers and children aged 6 months to 2 years. In India, the Indian Academy of Pediatrics Committee on Immunization (IAPCOI) recommends influenza vaccine in following groups:

- Congenital or acquired immunodeficiency
- Chronic cardiac, pulmonary, hematologic, renal, liver disease and diabetes mellitus
- Children on long-term aspirin therapy
- Any neurologic disease that might cause respiratory compromise or impair ability to clear secretions
- Asthma requiring oral steroids.

Vaccines should be stored at 2–8°C and never be frozen. The trivalent vaccines are licensed for use in children aged 6 months and older. Inactivated vaccines should be used in the at risk groups. As cases in tropical countries occur year-round vaccination should be given as soon as new vaccine becomes available. When vaccines are used for the first time in children aged 6 months to 9 years, two doses are recommended. After 9 years, a single dose only may be needed. Readers are referred to the IAP immunization guidebook for a detailed discussion about vaccinations.

Live attenuated influenza vaccination has an efficacy of up to 80% and around 33% effectiveness in preventing cases of disease in children over 2 years of age. This is lower in the inactivated vaccination (approximately 59% and 36%, respectively). Narcolepsy and febrile convulsions have been associated with some strains of the vaccination in children.

AVIAN INFLUENZA

Avian influenza, commonly referred to as bird flu, is a zoonotic disease, i.e., human infection with a viral strain which normally affects birds. However, there is a potential for human-to-human transmission. A highly pathogenic H5N1 strain of influenza has been responsible for outbreaks in birds (and some human cases) since 1997. This originated in Southeast Asia and spread westward. H5N1 is a fast mutating strain and is now panzootic (a disease affecting animals of many species over a wide area). Numerous countries across the globe have reported this strain in wild as well as farm birds. There have been further reports of avian influenza H5N1 in humans since 2003 prompting concerns that conditions are suitable for emergence of a pandemic strain. Two features of avian influenza H5N1 outbreaks are striking: (1) the predominance of children and young adults and (2) the high mortality rate.

In late March–April 2013, human cases of severe pneumonia caused by novel avian influenza A H7N9 infection in China were reported to the WHO. Most of these infections are believed to result from exposure to infected poultry or contaminated environments. Like H5N1 most affected individuals have had severe disease and the strain has been fatal in almost a third. At present, the WHO does not recommend antiviral chemoprophylaxis following exposure to H7N9 virus (exposure to live poultry environments contaminated with H7N9 or patients with H7N9 infection). Symptomatic individuals with exposure to H7N9 virus should receive prompt antiviral treatment with

a NA inhibitor. Prophylaxis may be considered in at risk (e.g., immunodeficient) asymptomatic individuals and health care workers with unprotected exposure.

IN A NUTSHELL

1. Influenza viruses are a significant cause of illness and hospitalization in children.
2. Younger children and those with chronic medical conditions are at increased risk of hospitalization from infection.
3. Influenza viruses are constantly evolving and this produces a challenge for vaccination programs and individual immunity.
4. Spread is by particle droplets and surface contact.
5. Cases are usually mild and can be asymptomatic. Secondary bacterial infection can cause serious illness such as pneumonia or otitis media.
6. Effective hand hygiene and contact restriction techniques using barrier methods can limit the spread of the virus.
7. Vaccines are based on recommended strains for an approaching season by the WHO. Trivalent inactivated vaccines are currently recommended by IAP in the at risk groups.
8. Antiviral agents can reduce symptom duration. Their widespread use and the supporting evidence have been questioned.

Chapter 31.16

Dengue

Piyush Gupta, Aashima Dabas

Dengue infection results in an acute febrile illness, caused by 4 closely related virus serotypes of the genus *Flavivirus*, family *Flaviviridae*. Dengue virus is transmitted to humans mainly by the *Aedes aegypti* mosquito. The disease is characterized by a biphasic fever, and may be associated with hemorrhagic manifestations. In 10–20% cases, the patient develops shock because of plasma leakage into the third space. Worldwide, children younger than 15 years comprise 90% of patients with dengue fever.

CLINICAL SPECTRUM

Dengue virus infection may be asymptomatic, lead to a benign illness, or present with severe manifestations. The World Health Organization (WHO) in 1997 classified symptomatic dengue virus infections in the following groups:

1. Undifferentiated dengue fever
2. Dengue fever. Defined as presence of fever of 2–7 days duration with any two of the following—myalgia, retro-orbital pain, headache, rash, arthralgia
3. Dengue hemorrhagic fever (DHF). A patient is classified as DHF if following four criteria were met: (i) fever or history of fever in last 2–7 days; (ii) bleeding tendencies—positive tourniquet test, petechiae, purpura, mucosal bleeds; (iii) thrombocytopenia—platelet count less than $100,000/\text{mm}^3$; and (iv) hemoconcentration [defined as $> 20\%$ rise in hematocrit (Hct)] or evidence of plasma leakage—pleural effusion, ascites or hypoproteinemia. The DHF was further graded in four stages (**Box 1**)
4. Dengue shock syndrome (DSS). All of above criteria plus hypotension.

BOX 1 Grading of dengue hemorrhagic fever (WHO, 1997)

Grade I: Fever, nonspecific complaints, positive tourniquet test, no spontaneous bleeds
Grade II: Spontaneous bleeds in addition to signs and symptoms of grade I
Grade III: Circulatory failure—cold clammy extremities, hypotension
Grade IV: Profound shock

Later, it was realized that this classification was at times difficult to apply in clinical settings, was not able to categorize all patients with dengue, and was missing out cases with severe dengue. Also, dengue fever and DHF may not be continuum of same disease and may exist as separate clinical conditions. WHO thus proposed a new classification for severity of dengue fever in 2009.

The new WHO classification has three severity categories: (1) dengue fever; (2) dengue fever with *warning signs*; and (3) severe dengue (**Fig. 1**). It is important to note that children without warning signs can also develop severe dengue.

- *Nonsevere manifestations* consist of a biphasic fever, generalized bodyache, rash, and a positive *tourniquet test*. These may or may not be associated with warning signs.
- *Warning signs* should be detected by close observation of the patient, so as to institute early and aggressive therapy. These include (1) abdominal pain or tenderness; (2) persistent vomiting; (3) clinical fluid accumulation (edema, pleural effusion, ascites); (4) mucosal bleeds; (5) hepatomegaly by greater than 2 cm; and (6) hemoconcentration as evidenced by increasing Hct with concomitant and rapid fall in platelet count.
- *Severe manifestations* include (1) severe hemorrhage; (2) profound shock; and (3) multisystem involvement. Presence of any one of these three criteria is sufficient for making a diagnosis of severe dengue infection.

Expanded dengue syndrome is a term introduced in 2011 which refers to unusual and severe involvement of liver, kidney, brain, or heart in association with dengue.

GEOGRAPHICAL DISTRIBUTION

Global

Dengue fever is known in the tropical Southeast Asia and Western Pacific for more than a century. The hemorrhagic form was first recognized in Philippines in 1953. Subsequently DHF was recognized in Thailand, India, Malaysia, Singapore, and Vietnam. In 1978, a big outbreak was reported from China resulting in 22,122 cases. In 1981, a large epidemic occurred in Cuba resulting in nearly 0.35 million cases of dengue fever. Out of these, 24,000 had DHF and 10,000 had DSS. Dengue has also been noticed in temperate regions of North America, Africa, and Mediterranean Europe.

As per current estimates, at least 100 countries are endemic for DHF and about 40% of the world populations (2.5 billion people) are at risk in tropics and subtropics. In 2010, 1.6 million cases of dengue were reported in the Americas alone, of which 49,000 cases were severe dengue. Recently, dengue has also been reported from Costa Rica, Mexico, France, Croatia and Portugal. Incidence of dengue infections annually has almost doubled from 50 million to 96 million (2010) in last few years.

India

India alone accounted for almost 34% of global dengue burden by 2010. Disease is prevalent throughout India in most of the metropolitan cities and towns. Outbreaks have also been reported from rural areas of Haryana, Maharashtra and Karnataka. During 1996, a severe outbreak of dengue/DHF occurred in Delhi wherein about 10,252 cases and 423 deaths were reported. In 2006, India witnessed another outbreak with 12,317 cases and 184 deaths in 21 states. The initial epidemics in India were due to serotype 2 or 4. The dengue serotype 1 was seen as predominant serotype in Delhi during 2007–2010. Concurrent infection of chikungunya and dengue serotype 2 has been reported from Vellore and Delhi.

ETIOLOGY

Dengue virus has at least 4 serotypes (1, 2, 3, and 4). These are antigenically very similar but do not offer a complete cross-protection after infection by either one of them. Infections in human by a serotype will produce lifelong immunity against reinfection by the same serotype. Subsequent infection (secondary infection) by another serotype results in severe dengue. The severity of epidemics caused by serotype 1 has been reported to be maximum followed by type 2 and 3.

EPIDEMIOLOGY

Vector

Aedes aegypti is the vector for dengue virus. Female mosquito bites the man during daytime. After feeding on a person with viremia, the female mosquito can transmit dengue immediately or after a period of 10–14 days (*extrinsic incubation period*). The extrinsic incubation period is a critical factor in successful transmission of the disease. A lower environmental temperature increases the extrinsic incubation period, which in turn, decreases the transmission. Once the mosquito becomes infective, it remains so till it dies.

The flight range of an adult *A. aegypti* mosquito is not more than 25–50 m in an urban environment. However, the vector can be transported by water, land, and air travel contributing to the transmission. For dengue transmission, the number of infected female mosquitoes per house is important. Usually this number is small, and in an Indian epidemic it was observed to be just 1 per household (*house index*). The minimum vector density, below which the dengue transmission ceases, is not known. The *A. aegypti* mosquito breeding is not necessarily related to the

ambient temperature. The mosquito has been found at altitudes as high as 2,200 m above the sea level. Vectors must survive longer than the sum of the initial nonfeeding period after birth (usually 2 days) and the extrinsic incubation period to be able to infect another human. Longevity under natural conditions ranges from 8 days to 42 days. The eggs of *A. aegypti* can survive without water for an year.

Host

People at all ages are susceptible to dengue. In Asians, disease is more severe in children. This is in contrast to America where infection mainly occurs in adults which is generally mild. Severe dengue occurs at high frequency in (1) infants; and (2) children having experienced a previous dengue infection. Other factors associated with increase host susceptibilities to severe disease include bronchial asthma; human immunodeficiency virus (HIV); certain human leukocyte antigen (HLA) types—HLA I (A04, A24, B0, B46), HLA II (DR1, DR4, DQ); polymorphisms in tumor necrosis factor-alpha (TNF- α); transforming growth factor-beta (TGF- β); vitamin D receptors; glucose-6-phosphate dehydrogenase deficiency and mutations in mannose-binding lectin-2 gene.

Environmental Factors

In many tropical countries, a positive association between rainfall or larval density and dengue incidence has been documented. The vector survives best at temperature 16–30°C and humidity of 60–80%. However, dengue epidemics have also been recorded in those areas where rainfall is unusually low. The transmission occurs only if the ambient temperature is above 16°C. Therefore, the transmission tends to decline when winter approaches. This is due to prolongation of extrinsic incubation period beyond the longevity of mosquito.

Transmission Risk Factors

When a member of a household is infected with dengue, other family members are at risk. Dengue spread is facilitated in any vector infested place where people congregate, such as schools, temples, cinema halls, offices, hospitals, factories, etc. In urban areas, the movement of infected people accounts for spread of virus than the movement of *Aedes* mosquito.

In utero transmission Dengue infection of pregnant women may result in passive transfer of antidengue immunoglobulin G (IgG) to the fetus or a congenital infection. These infants with maternal antibody are at a higher risk of developing severe dengue and many develop DHF during primary exposure.

PATHOGENESIS

Dengue virus infects the peripheral blood mononuclear cells within a few days of infective mosquito bite. Two patterns of immune response follow: (1) *primary* and (2) *secondary (anamnestic)*. Persons never previously infected with a flavivirus, nor immunized with a flavivirus vaccine (e.g., yellow fever, Japanese encephalitis), mount a primary IgM antibody response when infected with dengue virus, appearing within 2–3 days of defervescence and peaking at 2 weeks after the onset of symptoms. Antidengue IgG appears afterwards. Individuals with immunity due to previous flavivirus infection or immunization mount a secondary (anamnestic) antibody response when infected with dengue virus. In secondary flavivirus infections, which account for most cases of severe dengue, the dominant immunoglobulin is IgG; the levels of IgM being much lower.

Antibody against a strain of dengue virus does not protect from a different strain of virus. Rather, it may increase its capacity to multiply in human monocytes. The infected monocytes result in

activation of cross-reactive CD4+ and CD8+ cytotoxic lymphocytes. Cytotoxic lymphocytes mediate release of cytokines resulting in plasma leakage and hemorrhage.

PATHOPHYSIOLOGY

Two main pathophysiological changes occur in dengue. These are (1) *increased vascular permeability*, resulting in loss of plasma from the vascular compartment, hemoconcentration, low pulse pressure, and other signs of shock; and (2) disorder in the hemostasis involving thrombocytopenia, vascular changes, and coagulopathy.

Secondary dengue infection results in formation of immune complexes and activation of complement system. TNF- α , interferon, and interleukin-2 are elevated, and C1q, C3-C8, are depressed. As a result, vasoactive amines are released from the platelets. These cause massive release of water, electrolytes, and plasma proteins from the blood vessels and lead to hypovolemic shock. Increased vascular permeability is mediated through the nitric oxide pathway.

Platelet defects are both quantitative and qualitative. Thus, a patient with a normal platelet count may still have a prolonged bleeding time. Maculopapular and petechial rashes are present. In these lesions, dengue antigen, IgM and complement (C3) have been observed.

It may be noted that virus is usually not detectable in blood once shock manifests, though viral replication occurs in various organs.

CLINICAL FEATURES

Dengue infections have a wide clinical presentation. Following an incubation period of 3–7 days, the illness is characterized by three distinct phases: (1) febrile phase, (2) critical phase, and (3) phase of recovery.

Febrile Phase

This phase is characterized by a high-grade fever up to 104°F, abrupt in onset. Fever remains at the peak for 48–72 hours before it starts declining. It is accompanied with nonspecific constitutional symptoms such as generalized myalgia, body ache, anorexia, nausea, vomiting, and headache. Parents may notice an erythematous rash, especially over the extremities. Some children may have associated sore throat, or arthralgia. These features, by themselves, are however not sufficient enough to arrive at a diagnosis of dengue fever. Dengue should be strongly suspected, if above features are associated with mild hemorrhagic manifestations including petechial hemorrhages, mucosal bleeds, or a positive tourniquet test. Presence of tender hepatomegaly (without obvious icterus) strongly favors possibility of dengue infection. The febrile phase lasts for 2–3 days.

Complication High fever in this phase can cause dehydration, febrile delirium, and febrile seizures in children less than 5 years of age.

Critical Phase

Onset of the critical phase is closely linked to the time of defervescence that occurs by third day of illness. All children in defervescence phase need to be closely monitored for the *warning signs* as described earlier. Those manifesting with one or more of these signs are likely to enter the critical phase. Not all children with dengue infection enter this phase. Many children improve progressively after defervescence (nonsevere dengue).

Critical phase is characterized by an increase in capillary permeability. This is preceded by a fall in the platelet count. Increased capillary permeability results in leakage of plasma into

the third space. Clinically, this manifests as polyserositis, i.e., pleural effusion and ascites. Plasma leakage from the intravascular compartment into the third space results in hemoconcentration in the vascular bed, reflected by a rising Hct. Increase in Hct is directly proportional to the volume of plasma lost from the vascular compartment.

Epigastric discomfort, tenderness at right costal margin, and generalized abdominal pain are common. Liver becomes palpable. Petechiae may be present over extremities, axillae, face, and palate.

Leakage of a significant volume of plasma leads to hypovolemia, hypoperfusion, and shock. Hypoperfusion may result in multiple end-organ impairment, metabolic acidosis, and disseminated intravascular coagulation (DIC). Consumption coagulopathy results in hemorrhage that may cause a fall in Hct. End-organ impairment manifests with hepatitis, myocarditis, or encephalitis. Children developing profound shock, severe hemorrhage, or multisystem involvement are at higher risk of mortality and thus are said to be having *severe dengue infection*. These children need aggressive management. This phase lasts for 48 hours.

Recovery Phase (Plasma Reabsorption Phase)

Plasma starts coming back to the intravascular compartment, provided the patient survives the critical phase of plasma leakage and shock. Onset of this phase is characterized by an improvement in general well-being and appetite. Urine output improves, and pain abdomen subsides. Though this is the phase of improvement, child should be monitored carefully for hypervolemia. Reabsorption of leaked plasma plus administration of excess intravenous (IV) fluid may result in fluid overload, pulmonary edema, and congestive heart failure, manifesting as dyspnea, tachycardia, and raised jugular venous pressure. Cardiovascular manifestations (bradycardia, arrhythmias) are also reported during this phase. Hct value either normalizes or may show a decline below normal. Platelet count starts improving. This phase lasts for 48–72 hours. Thus, most patients with dengue fever run a typical course of disease lasting from 7 days to 10 days (**Fig. 2**).

Severe Dengue

Children and adolescents with severe dengue have a more protracted course and recovery may take 10–14 days. Dengue shock is characterized by a narrow pulse pressure less than or equal to 20 mm Hg, cold extremities, delayed capillary refill time, weak

Figure 2 The course of dengue illness
(Reproduced with permission of the publisher from: *Dengue, Guidelines for Treatment, Prevention Control*. Geneva: WHO; 2009)

pulse, and tachycardia. Skin becomes cool, blotchy, congested. Typically, consciousness is not altered. Major bleeding can occur from gastrointestinal tract or brain. Organ impairment manifests as hepatic failure, renal failure, myocarditis, or encephalopathy. Atypical manifestations include acute inflammatory colitis, uveitis, myositis, Guillain-Barré syndrome, and Kawasaki disease.

DIAGNOSIS

Hematological Tests

The clinical diagnosis is corroborated by raised hematocrit (Hct) and thrombocytopenia:

- An Hct level rise of greater than 20% is a sign of hemoconcentration and precedes shock. The Hct level should be monitored at least every 24 hours to facilitate early recognition of *warning signs* and every 3–4 hours in *Severe dengue*.
- Thrombocytopenia occurs in up to 50% of children with dengue. Platelet counts of less than 100,000 cells/ μ L indicate onset of *critical phase* and typically occur before defervescence and the onset of shock. The platelet count should be monitored at least every 24 hours initially.
- The white blood cell count can be normal or show leukocytosis during initial phase. Leukopenia, often with lymphopenia, precedes thrombocytopenia and is observed near the end of the febrile phase of illness.

Biochemical Profile

Prothrombin time is prolonged. Activated partial thromboplastin time is prolonged. Low fibrinogen and elevated fibrin degradation product levels are signs of DIC. Hyponatremia is the most common electrolyte abnormality in critical phase. Metabolic acidosis and elevated blood urea is observed in those with shock. Serum glutamic pyruvic transaminase (SGPT) levels elevated. Low serum albumin levels are a sign of hemoconcentration.

Serodiagnosis

Serum specimens should be sent to the laboratory for serodiagnosis, polymerase chain reaction (PCR), and viral isolation. Because the signs and symptoms of dengue fever are nonspecific, attempting laboratory confirmation of dengue infection is important. Serodiagnosis is based on (1) detection of viral nonstructural protein 1 (NS1) during initial illness; (2) detection of IgM antibodies to dengue; or (3) fourfold rise in dengue IgG in paired samples. **Table 1** outlines the desired timing of these tests for confirming the diagnosis. Laboratory criteria for definitive diagnosis include one or more of the following:

1. Isolation of the dengue virus from serum, plasma, leukocytes, or autopsy samples

Table 1 Diagnostic tests for dengue fever

Diagnostic method	Timing of test (after disease onset)	Validity
Virus isolation (culture)	1–5 days	++++
Genome detection (PCR)	1–5 days	++++
Antigen detection (NS1)	1–5 days	+++
Antibody detection (IgM) after 5 days*		++
IgG (paired sera)**	Acute sera 1–5 days; convalescent sera after 15 days	+

*IgM positivity rates: by 3–5 days (50%), 5–7 days (80%), 10 days (90%). IgM appears between 3 days and 10 days and disappears by 2–3 months.

**IgG appears after 1–2 weeks and may persist for life.

2. Demonstration of a fourfold or greater change in reciprocal IgG or IgM antibody titers to one or more dengue virus antigens in paired serum samples. IgM antibody appears early in disease course, requires single sample and is less cross-reactive to other flaviviruses. Thus, measurement of an IgM appears to be most prudent. As per the National Vector Borne Disease Control Programme (NVBDCP), the laboratory test being followed is the IgM antibody-capture enzyme-linked immunosorbent assay (MAC-ELISA) for dengue virus
3. Demonstration of dengue virus antigen in autopsy tissue via immunohistochemistry or immunofluorescence or in serum samples via enzyme immunoassay
4. Detection of viral genomic sequences in autopsy tissue, serum, or cerebral spinal fluid (CSF) samples via PCR.

MANAGEMENT

The mainstay of treatment is supportive therapy. Increased oral fluid intake is recommended to prevent dehydration. Supplementation with IV fluids may be necessary to prevent dehydration and significant hemoconcentration. Fever is managed with paracetamol. Aspirin and nonsteroidal anti-inflammatory drugs should be avoided as these drugs may worsen the bleeding tendency associated with some of these infections. Shock is managed with isotonic fluids. Packed cell transfusion is indicated in refractory shock or if there is significant bleeding.

Patients with known or suspected dengue fever should have their platelet count and Hct measured daily from the third day of illness until 1–2 days after defervescence. Patients with a rising Hct level or falling platelet count should be monitored more frequently. Management of dengue illness can be discussed in three steps:

Step 1: Overall assessment

Step 2: Diagnosis and severity assessment

Step 3: Categorizing into group A, group B, or group C, and treating accordingly.

Overall Assessment

History and Examination

Emphasis in history should be on assessment of *warning signs*. Physical examination should concentrate on hemodynamic assessment, so as to determine the presence and extent of shock, confirming or detecting the warning signs; and checking for bleeding manifestations, abdominal tenderness, mental state and hydration. Tourniquet test is a must.

Investigations

Initial investigations should include an Hct, WBC count, platelet count, and tests to confirm the diagnosis, as described in the section on laboratory diagnosis. In critical phase, additional tests need to be done and include liver function test, renal function test, chest X-ray, serum electrolytes, and ultrasound abdomen.

Diagnosis and Severity Assessment

Determine the phase of disease (febrile, critical, recovery) and severity (nonsevere, severe) of dengue, as per criteria outlined earlier. The child will need admission if any of the following criteria is fulfilled:

1. Presence of any of warning signs
2. Signs and symptoms of hypotension
3. Bleeding from any site
4. Renal, hepatic, or central nervous system (CNS) involvement
5. Pleural effusion or ascites
6. Rising Hct
7. Platelet count less than 50,000/ mm^3 .

Categorize Patients in Group A, B, or C (Table 2)

This step is aimed to place the patient in an appropriate Group (A, B, or C) to decide on future course of action, as follows:

Group A: Patients, who may be sent home

Group B: Patients needing hospitalization

Group C: Patients requiring emergency treatment.

Group A: Home Management

All children who are tolerating oral fluids, passing urine at least once in 6 hours, and not having any of the warning signs can be sent home. Following management needs to be advised:

- Encourage fluid intake; can give oral rehydration salt (ORS), fruit juice, etc. The parents should be advised to increase the amount of oral fluids to be given (e.g., 3–10 kg: 100 mL/kg and 10–20 kg: 75 mL/kg)
- Paracetamol (15 mg/kg/dose) if the child is uncomfortable because of fever. Avoid aspirin, ibuprofen, mefenamic acid, and nimesulide
- Monitor at home for fluid intake, urine output, fever, obvious bleeding, and altered sensorium
- Bring back if any of the above is present or the child develops any of the warning signs.

Group B: Hospital Management

Any patient who fulfills the admission criteria should be admitted (as mentioned above). They may or may not have warning signs. A baseline Hct is measured and monitoring is started. In cases where no warning signs are present, patients should be started on maintenance fluids with isotonic fluid. If patient shows signs of mild dehydration, a correction of 50 mL/kg (< 12 months) and 30 mL/kg (> 12 months) is added to main fluid. At all times clinical parameters are closely monitored and correlated with Hct to guide further fluid therapy. For those who present with warning signs, the following is advised:

Table 2 Treatment of dengue

Category	Patient characteristics	Treatment
A	Accepting orally, passing urine adequately and no warning signs*	<i>Home therapy</i> <ul style="list-style-type: none"> • Increased oral fluids, paracetamol
B	Warning signs* present	<i>Hospitalize</i> <ul style="list-style-type: none"> • Monitor hematocrit, platelets, vitals • Intravenous fluids: titrated as per hematocrit • If worsens, manage as category C
C	Severe bleeding Severe shock Severe organ dysfunction: hepatic, CNS, heart, kidney	<i>Intensive care</i> <ul style="list-style-type: none"> • Monitor hematocrit, platelets, vitals • Treatment of shock: normal saline bolus • Blood transfusion for severe bleeding or clinical worsening. Judicious use of platelets • Supportive treatment for organ failure • Watch for signs of fluid overload, and treat, if detected (oxygen 2, frusemide)

*Warning signs: Abdominal pain, persistent vomiting, mucosal bleed, hepatomegaly, clinical fluid accumulation, lethargy, hemoconcentration, thrombocytopenia

- Start isotonic IV fluids (normal saline or Ringer's lactate) at 5–7 mL/kg/hour for 1–2 hours, reduce to 3–5 mL/kg/hour for 2–4 hours, and then continue with 2–3 mL/kg/hour, according to the response
- Reassess Hct and clinical status
 - If same, continue with 2–3 mL/kg/h for another 2–4 hours
 - If clinical status worsens or Hct rises, increase rate of fluids to 5–10 mL/kg/hours for 1–2 hours
- Reassess clinical status, repeat Hct and review fluid infusion rates, till the child is better
 - If the child improves, maintain minimum IV fluids at 0.5 mL/kg/hour for 24–48 hours. Stop fluids when child demands and accepts adequate oral fluids, and food
 - Those who worsen or develop profound shock, bleeding or multisystem involvement, manage as for Group C.

Group C: Emergency Treatment

Emergency treatment is required in children with severe dengue or those in critical phase, as follows:

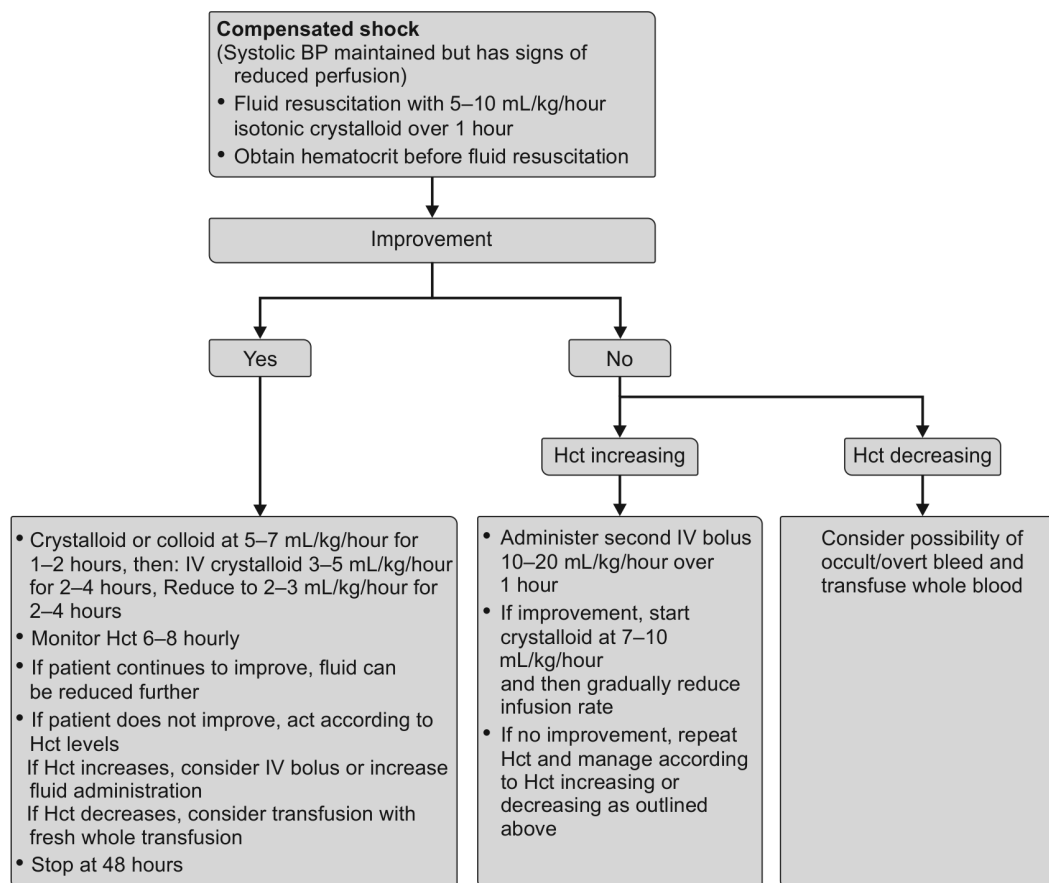

- Obtain Hct, blood count, and other organ function tests, as indicated.
- *Compensated shock:* In these children, fluid resuscitation is started at 5–10 mL/kg/hour, and further directed as per **Flow chart 1**.
- *Hypotensive shock:* Administer isotonic fluid bolus 20 mL/kg in 15 min. For further management, follow the algorithm depicted in **Flow chart 2**.
- *Hemorrhagic complications:* Suspect severe bleeding if there is an unexplained fall in Hct, refractory shock not responding to 40–60 mL/kg of fluid, and persistent or worsening metabolic acidosis. Packed cell transfusion 10 mL/kg over 2–3 hours can be lifesaving in these children. There is not much evidence for platelet transfusion or fresh frozen plasma for severe bleeding. Platelet transfusions should not be used prophylactically. Its use has neither shown to prevent progression to severe bleeding nor does it shorten the bleeding time and may instead be associated with severe side effects. Platelet transfusion should be restricted to cases with severe bleeding only.
- *Monitoring:* This essentially remains the basic prerequisite for treating children with severe dengue, in an emergency setting.
 - Monitor vital signs and peripheral perfusion 1–4 hourly unless patient is out of critical phase. Monitor Hct before and after fluid replacement, then 6–12 hourly.
 - Monitor blood glucose and other organ dysfunction both clinically and biochemically.
 - A typical monitoring chart for dengue fever should record the following: body temperature, heart rate, blood pressure, pulse volume, capillary refill time, abdominal pain, appetite, abdominal pain, vomiting, bleeding and sensorium.

Treatment of Fluid Overload

A patient with dengue can have fluid overload due to excessive or rapidly transfused IV fluids, use of hypotonic fluids, and inappropriate use of fresh frozen plasma or platelets. Another important reason is continuation of IV fluids even during the phase of plasma reabsorption and recovering.

These children may present with features of pulmonary edema or congestive heart failure. Following management is suggested:

- **Oxygen Management of Other Complications**
Encephalopathy in dengue may result due to intracranial bleeding, electrolyte disturbances, occlusion due to DIC or hepatic encephalopathy. Appropriate diagnosis for cause and specific

Flow chart 1 Algorithm for fluid management in compensated shock

management should be instituted. Cardiac involvement may be seen during shock or during convalescence, which may manifest as arrhythmias or heart failure.

Criteria for Discharge

Patient should be discharged only if he has been afebrile for at least 24 hours, passing urine normally, having improved appetite and has no respiratory distress. His laboratory parameters should show a stable Hct and platelet count of more than 50,000/mm³.

PREVENTION AND CONTROL

Aedes aegypti should be the main target of surveillance and control. The NVBDCP was launched in 2003 which extended vector control services for dengue and Japanese encephalitis. A mid-term plan was approved in 2011 to enhance the country's capacity to control dengue. The activities targeted against dengue include:

- Increasing diagnostic facilities. Introduction of ELISA-based NS1 antigen for diagnosis of dengue early in disease
- Monitoring and surveillance of vector control
- Capacity building of medical health personnel
- Increasing social mobilization through information, education and communication (IEC) activities for vector control.

Surveillance

Disease Surveillance

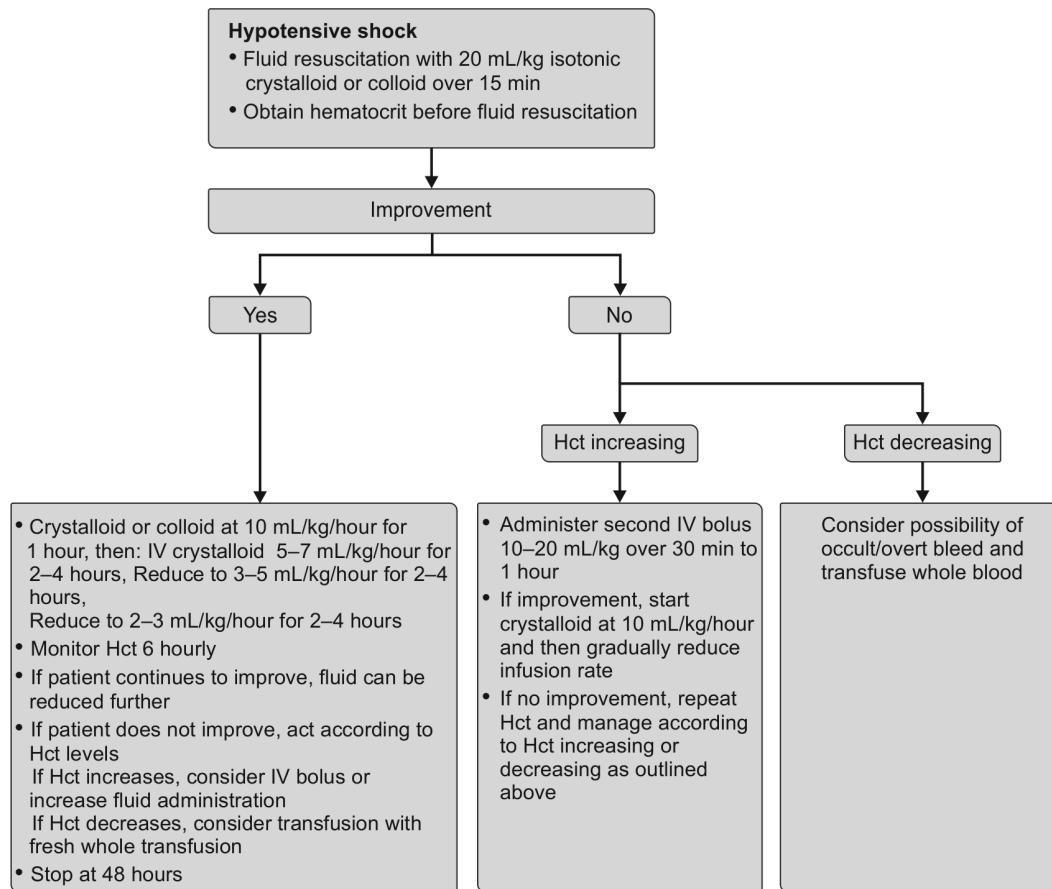

Tracking the number of suspected and confirmed infected human cases. It also includes recording the circulating serotypes of dengue and the number of deaths from dengue.

Vector Surveillance

Tracking mosquito populations in areas of potential risk. Mainly two indices are used for measuring the vector density. These are (1) *house index*; and (2) *Breteau index*. House index is defined as the percentage of houses positive for the larvae; and Breteau index as the number of containers positive for the larvae per 100 houses. These indices measure larval infestation rather than adult mosquito density. Epidemic spread of *Aedes* has been reported with *house index* as low as 1% in Indian settings.

Monitoring Behavioral Impact

Communication for behavioral impact (COMBI) is a methodological process where communication interventions are used to help a community adopt healthy behaviors aimed to reduce mosquito multiplication and spread. The surveillance is done by observing whether such behaviors are adopted and sustained by the community.

Flow chart 2 Algorithm for fluid management in hypotensive decompensated shock

Long-term Vector Control

Adequate water supply is a must. Sprays of larvicides are recommended in high-risk localities. All objects that may collect water (old tyres, broken jars, empty tins and bottles) should be disposed off. Water should be changed routinely in water coolers, flower vases, and overhead tanks. Coolers, if not in use should be drained and mopped dry. Large tanks with taps should be kept covered. Management of roof tops, porticos and sunshades to be encouraged. Health education should be provided regularly in schools and through mass media. Sensitize and involve the community for detection of *Aedes* breeding places and their elimination.

Biological and Chemical Control

Use of larvivoracious fish in ornamental tanks, fountains, or biocides can kill the larval stages. Use chemical larvicides like *Abate*® in big breeding containers. Aerosol space spray during daytime may be another option in high-density areas. There has been recent research exploring the control of *Aedes* mosquito by genetically engineering male insects which carry dominant lethal gene (RIDL) at both pupa and adult stages.

In recent years, interest in mosquito-killing (entomopathogenic) fungi is reviving, mainly due to continuous and increasing levels of insecticide resistance and increasing global risk of mosquito-borne diseases. Particular focus is on species belonging to the genera *Lagenidium*, *Coelomomyces*, *Entomophthora*, *Culicimycetes*, *Beauveria*, and *Metarhizium*.

Vaccine Development

Development of a multivalent vaccine against all four serotypes seems necessary. Progress in vaccine development is slow because these viruses grow poorly in cell culture and there is no acceptable animal model for dengue illness.

A live attenuated tetravalent dengue vaccine (CYD-TDV) has been developed which contains four dengue virus with expression of dengue premembrane and envelope protein and nonstructural and capsid protein of yellow fever strain (YF-17D). The vaccine is administered as three dose schedule and has shown good protection against dengue serotype 1, 3 and 4. The vaccine is still under multicentric phase III trials. Several research groups are successfully exploring an infectious clone technology for the development of a dengue vaccine. The Chimeri Vax™ system, originally developed to construct JE vaccine, has now been applied to dengue viruses. This vaccine was shown to be safe and immunogenic in a monkey study. Another approach is based on the use of a dengue type 4 mutant containing a deletion for the construction of a dengue chimeric vaccine. Phase I clinical trials of a deletion mutant carried out in adult humans showed good safety and immunogenicity.

In India, the yeast, *Pichia pastoris* has been used to develop a noninfectious dengue virus like particle consisting of viral envelope protein using recombinant DNA technology. The vaccine is under trial.

IN A NUTSHELL

1. Dengue is spread by *Aedes* mosquito which multiplies in collections of stagnated water.
2. Four different serotypes of virus exist. Antibody against one serotype does not confer protection against another. Rather, the illness is more severe following secondary infection in a child sensitized against a different serotype earlier.
3. Increased capillary permeability and coagulopathy chiefly contribute to disease manifestations. Thrombocytopenia occurs both due to bone marrow suppression and immune-mediated destruction.
4. Clinical presentation consists of a biphasic fever, myalgia, arthralgia, and hemorrhagic manifestations, lasting over 3–7 days. The most vulnerable stage is soon after defervescence (critical phase) characterized by increased capillary permeability.
5. Serological diagnosis is possible by detecting nonstructural (NS) antigen 1 between 2 days and 5 days, detection of IgM antibodies between 5 days and 10 days, or fourfold rise in IgG antibodies after 7–10 days.
6. Children with *warning signs* should be hospitalized. Those with severe shock, severe bleeding and organ involvement need management in intensive care unit (ICU) setting.
7. Fluid therapy is the mainstay of treatment. Crystalloid is the fluid of choice during resuscitation. Best guide to fluid therapy is Hct.

Chapter 31.17

Chikungunya Fever

Rajniti Prasad

Chikungunya, a viral fever, is caused by an alphavirus [chikungunya virus (CHIKV)] and spread by bite of an infected *Aedes aegypti* mosquito. The disease was first described in 1955 following an outbreak on the Makonde plateau. The name derives from kungunyala, meaning *to dry up or become contorted*. Although primarily African and zoonotic disease, non-African large urban outbreaks have been reported, which is transmitted by the same vectors as those of dengue viruses. Since then, CHIKV has caused numerous outbreaks and epidemics in both Africa and Southeast Asia, affecting many children.

CHIKUNGUNYA VIRUS

Chikungunya virus, a positive strand, enveloped RNA virus, is a member of the alphavirus of *Togaviridae* family. It is closely related to o'nyong-nyong viruses. Three distinct phylogroups were reported on the basis of E1 envelope glycoprotein gene sequence: first contained all isolates from West Africa, second comprised all Central, Southern and Eastern African (CSEA) strains and third isolates from Asia. Complete genomic sequence of CHIKV has 11,805 nucleotides in length. Coding sequences consist of two large nucleotides, encoding the nonstructural polyprotein and structural polyprotein. The nonstructural polyprotein is the precursor of proteins nsP1, nsP2, nsP3 and nsP4 and structural polyprotein is the precursor of protein C, E2, E3, 6K and E1.

EPIDEMIOLOGY

The outbreak of CHIKV is being reported from different parts of India. The current outbreak in India started in late 2005, when cases of suspected fever were reported from coastal parts of Andhra Pradesh and Karnataka. The confirmed cases of chikungunya fever have been reported from all over India but more so from Andhra Pradesh, Karnataka, Maharashtra, Tamil Nadu, Madhya Pradesh and Gujarat states. The attack rate varies from 8% to 45%.

VECTOR

Aedes aegypti, *A. albopictus* and *A. polynesiensis* are commonly involved in the transmission of virus, although *Culex* has also been reported for the transmission. *A. aegypti* is the principal vector of CHIKV in India. This vector is anthropophilic, endophagic and bites during the daytime. It mainly breeds in man-made containers such as coolers, cisterns, wells, water-storage containers, etc. Both *A. aegypti* and *A. albopictus* are present in the United States of America and Europe, thus virus could expand to new geographic locations.

TRANSMISSION

Chikungunya virus is commonly transmitted to humans through the bite of infected *Aedes* mosquitoes. Vertical transmission, occupational exposure and occurrence in a health worker from careless handling of patient's blood have also been reported. In Africa, monkeys and other wild primates may also serve as reservoirs of the virus.

PATHOGENESIS

Chikungunya virus replicates in fibroblasts, monocytes, macrophages, natural killer cells, epithelial and endothelial cells.

T and B lymphocytes and monocyte-derived dendritic cells are not susceptible. Viral entry occurs through a pH-dependent, endocytic pathway. CHIKV is highly cytopathic for mammalian cells, and causes apoptosis of infected cells. The replication of virus is inhibited by interferon. In humans, CHIKV produces clinical manifestations about 48 hours after mosquito bite. Patients have high viremia during the first 2 days, declines around day 3 or 4 and usually disappear by day 5. Hemagglutination inhibition and neutralizing antibodies can be detected after day 5 with declining viremia. Silent CHIKV infections do occur. A single infection; clinical or silent confers lifelong immunity. The enhanced expression (upregulation) of cytokines such as interleukin (IL)-1 and IL-6 is associated with severe CHIKV-induced disease.

CLINICAL MANIFESTATIONS

Chikungunya is an acute infection characterized by acute onset of high fever, severe arthralgia, myalgia and skin rash lasting for a period of 1–7 days (triad: fever, rashes and arthralgia). The incubation period is usually 2–4 days, with a range of 1–12 days. All age groups are affected. Fever rises abruptly, often reaching 39–40°C accompanied by chills, myalgia, headache and photophobia. This acute phase lasts 2–3 days. The temperature may remit for 1–2 days, after a gap of 4–10 days (saddleback fever).

The arthralgia is polyarticular, migratory and predominantly affects the small joints of hands, wrists, ankles, elbows and feet with lesser involvement of larger joints. In acute stage, children complain severe pain on movement and bending forward (**Fig. 1**). Pain is worse in the morning, improved by mild exercise and exacerbated by strenuous exercise. Swelling may occur but fluid accumulation is uncommon. About 12% of serologically positive cases have been reported to have residual joint symptoms such as joint stiffness, swelling and pain 3 years after initial infection.

Cutaneous manifestations include flushing of the face and trunk. This is usually followed by maculopapular rash and occasionally petechiae. Trunks and limbs are commonly involved,

Figure 1 Frequency of pain by location during acute stage of chikungunya infection

but face, palms and soles may also show lesions. Rashes may simply fade or desquamate. Exacerbation of existing dermatoses such as psoriasis, and Hansen's disease have been observed.

Iridocyclitis and retinitis are the most common ocular manifestations and have benign clinical course. Less frequent ocular lesions include episcleritis. Diarrhea, vomiting and abdominal pain have been reported in about 50% of patients. Neurological manifestations include acute encephalopathy, encephalitis, febrile seizure, acute flaccid paralysis and Guillain-Barré syndrome. Other manifestations include congestive cardiac failure, pneumonia, fulminant hepatitis, acute kidney injury and respiratory failure. Hemorrhagic manifestations are rare, but are an important distinguishing feature from dengue fever.

The majority of children develop chronic stage of the disease, which is characterized by pains in joints and/or bones or both exacerbation and remission. The case fatality rate is about 1 in 1,000 during epidemics. The common causes of death are heart failure, multiple organ failure, hepatitis and encephalitis.

DIAGNOSIS

The diagnosis of chikungunya is based on clinical, epidemiological and laboratory findings. However, an acute onset of fever and severe arthralgia or arthritis in children unexplained by other medical disorder should be considered as possible case of chikungunya. Laboratory investigation is essential to establish diagnosis and initiate specific public health response. Three main laboratory tests used for diagnosis of chikungunya fever include (1) virus isolation, (2) polymerase chain reaction (PCR) and (3) serological tests.

Virus isolation is the most definitive tests. CHIKV produces cytopathic effects in a variety of cell lines including BHK-21, HeLa and Vero cells. The cytopathic effects must be confirmed by CHIK specific antiserum and results can be available in 1–2 weeks. *Reverse transcriptase PCR* (RT-PCR) technique for diagnosis has been developed using nested primer pairs amplifying specific components of three structural gene regions, capsid (C), envelope E2 and part of envelope E1. RT-PCR can detect viral nucleic acid in blood 1 day before to 7 days after onset of symptoms. PCR results can be available within 1–2 days.

Serologic diagnosis can be made by demonstration of fourfold increase in antibody in acute and convalescent sera or demonstrating immunoglobulin M (IgM) antibodies specific for CHIKV. A commonly used test is IgM antibody-capture enzyme-linked immunosorbent assay (MAC-ELISA). Results of MAC-ELISA can be available within 2–3 days. Cross-reaction with other flavivirus antibodies such as O'nyong-nyong and Semliki may occur; however, the latter viruses are relatively rare in Southeast Asia. Further confirmation can be done by neutralization tests and hemagglutination inhibition assay (HIA). A positive virus culture supplemented with neutralization is taken as definitive proof for the presence of CHIKV. The diagnostic criteria of chikungunya fever are summarized in **Table 1**.

MANAGEMENT

There is no specific treatment for chikungunya fever. The illness is usually self-limiting and resolves with time. Supportive care with rest is recommended during the acute stage. Movement and mild exercise tend to improve stiffness and morning arthralgia, but heavy exercise may exacerbate symptoms. Nonsteroidal anti-inflammatory drugs (NSAIDs) are recommended. In unresolved arthritis refractory to NSAID, chloroquine (10 mg/kg/day) has proved to be useful. Chloroquine inhibits viral replication by

Table 1 Diagnostic criteria of chikungunya fever

Criteria	Definition
<i>Clinical</i>	<i>Possible case:</i> When not explained by other medical condition: dengue or alphavirus infection, arthritic disease, endemic malaria
• Acute onset of fever > 38.5°C and severe arthralgia or arthritis	
<i>Epidemiological</i>	<i>Probable case:</i> If clinical and epidemiological criteria are met: other pathogens with similar clinical manifestations can cocirculate within the same geographical regions
• Residing in or visited epidemic area within 15 days before onset of symptoms	
<i>Laboratory</i>	<i>Confirmed case:</i> If a patient tests positive for one of the laboratory, irrespective of clinical manifestations
• Virus isolation	
• Presence of viral RNA	
• Specific IgM antibodies	
• Fourfold increase in IgG titers in paired samples	

blocking the pH-dependent endocytosis of CHIKV into host cells. Although chloroquine blocks CHIKV replication, the therapeutic (antiviral) index of chloroquine in cell cultures is narrow thus, one should be cautious when planning the use of chloroquine. Ribavirin has some antiviral activity and showed moderate beneficial effect in alleviating arthralgia and swelling. Although ribavirin has some antiviral properties against CHIKV, interferon- α is more effective in inhibiting CHIKV replication.

Self-resolution occurs with cutaneous lesions. Patients with hyperpigmentation may be treated with sunscreens and topical steroids and improve over 3 weeks. Patients with more diffuse involvement showed a slower resolution. Aphthous ulcers usually heal over 7–10 days with local cleaning and topical antimicrobials. Iridocyclitis and retinitis usually have a benign clinical course and do not require any treatment. Vision is usually preserved.

Infected persons should be protected from further mosquito exposure (staying indoors and/or under mosquito net during the first few days of illness) so that they cannot contribute to the transmission cycle.

PREVENTION AND CONTROL

Prevention is mainly aimed to avoid mosquito bites and elimination of mosquito breeding sites including use of full sleeve clothes and long dresses to cover the limbs, mosquito coils, repellents and electric vapor mats during the daytime. Use of permethrin-treated mosquito nets to protect babies, old people and others who may rest during the day. Drainage of water from coolers, tanks, barrels, drums and buckets when not in use is advocated.

Vaccine

The widespread geographic distribution, recurrent epidemics and infection of military personnel, travelers, and laboratory staff working with CHIKV have indicated the need for a safe and efficacious vaccine. In Thailand, CHIK strain 15561 was used to develop a small lot of vaccine. The vaccine produced no untoward reactions and was highly immunogenic. The current live vaccine (Lot 1-85, TSI-GSD-218) was developed in the United States in the US Army Medical Research Institute of Infectious Diseases (USAMRIID) and was produced at the Salk Institute, from GMK strain 15561 by serial passage in MRC-5 cells. The results of phase I and phase II trials strongly suggest that the live vaccine is safe and well-tolerated and produces no severe or frequent symptoms.

IN A NUTSHELL

1. Chikungunya is caused by an alphavirus (CHIKV) and spread by bite of an infected *A. aegypti*.
2. The classical triad consists of fever (saddleback type), maculopapular rashes and arthralgia.
3. Arthralgia is polyarticular, migratory and predominantly affects the small joints of hands, wrists, ankles, elbows and feet.
4. The diagnosis is based on clinical, epidemiological and laboratory findings, which include virus isolation, PCR and serological tests.
5. It is a self-limiting disease and resolves with time. Supportive care with rest is recommended during the acute stage. NSAIDs are recommended. In unresolved arthritis refractory to NSAID, chloroquine (10 mg/kg/day) has proved to be useful.

Chapter 31.18

Viral Hemorrhagic Fevers

Nigam Prakash Narain, Priya Verma

Viral hemorrhagic fevers (VHFs) refer to diseases caused by distinct families of enveloped RNA viruses. The disease process encompasses a multisystem involvement with breakdown of the entire vascular machinery of the body and the mechanisms that regulate the body's internal homeostasis; with widespread hemorrhage that represents these infections. Some of these viruses cause relatively mild illnesses, but in most cases the disease is fatal. VHF viruses are enveloped viruses with single-stranded RNA genomes and vary greatly in their morphology. They are members of four distinct families: (1) *Arenaviridae*—Lassa, Junin, Machupo, Sabia and Guanarito viruses; (2) *Bunyaviridae*—Rift valley fever (RVF), Crimean-Congo hemorrhagic fever (CCHF) and agents of hemorrhagic fever with renal syndrome; (3) *Filoviridae*—Ebola and Marburg viruses; and (4) *Flaviviridae*—yellow fever, Kyasanur forest virus, dengue, Omsk and Alkhurma viruses. Some of the hemorrhagic fever viruses viz. Ebola, Marburg, Lassa fever and the New World arenaviruses have a propensity to cause infection through aerosol dissemination that makes them formidable candidates as weapons for biological warfare. In this chapter, we shall focus only on these VHF viruses. Dengue fever is already discussed.

EPIDEMIOLOGY

The VHF viruses are associated with sporadic disease and epidemics. The natural reservoir of these viruses is a nonhuman vertebrate or an arthropod. Humans are incidental hosts.

Arenaviridae

The viruses causing hemorrhagic fevers are broadly distributed over two continents. Lassa virus is endemic to the region of West Africa while the viruses endemic to the South American continent viz. Junin, Machupo, Guanarito and Sabia viruses are collectively referred to as the Latin American hemorrhagic fever viruses.

Bunyaviridae

Rift valley fever is endemic to sub-Saharan Africa. It caused large epidemics in Kenya and Somalia in 1997–1998, Tanzania 2006–2007 and in the South African nations of Botswana and Namibia in 2010.

Filoviridae

Marburg virus was first isolated in 1967 from cases of hemorrhagic fever in European laboratory workers working with tissues from African green monkeys imported from Uganda. Ebola virus was first reported in Zaire and Sudan and was associated with high case fatality rates. Subsequently a third subtype Ebola (Reston) and a fourth subtype were found in an animal worker in Côte d'Ivoire. Fruit bats are the natural reservoirs for filoviruses. The Marburg virus and subtypes of Ebola Sudan, Zaire and Côte d'Ivoire are restricted geographically to the African continent.

Flaviviridae

Kyasanur forest virus was discovered in a sick monkey in the Kyasanur forest in India in 1957. Annual cases reported are approximately 400–500. The yellow fever virus is endemic to the sub-Saharan African regions. Annual incidence is estimated to be 200,000 cases globally. Dengue virus is prevalent throughout Asia and Africa.

TRANSMISSION

The routes of transmission of the VHF viruses are variable but most are zoonotic with spread via arthropod bites or contact with infected animals. The viruses are carried in rodents and transmitted through the urine, saliva and other body excretions from infected rodents. Zoonotic spread may occur through:

- Livestock via consumption of raw meat from potentially infected animals and unpasteurized milk (RVF virus)
- Rodents via inhalation of aerosols or contact with rodent excreta (arenavirus, hantavirus)
- Other reservoir species such as bats (Ebola and Marburg viruses).

Vector-borne transmission also occurs via mosquitoes, *Aedes* (RVF virus, yellow fever) or tick bites or crushing of infected ticks [CCHF, Kyasanur forest disease (KFD)]. Person-to-person spread is another important mode of transmission for many of the viruses especially the filoviruses through contact with infected blood and body secretions. Nosocomial transmission may also occur through the reuse of needles, syringes and exposure to infected body fluids and hospital waste as a fallout of nonadherence to infection control measures in a hospital setting.

PATHOGENESIS

The viral agents causing severe hemorrhagic fevers are all single-stranded RNA viruses that can infect man either through contact with animal reservoirs or arthropod vectors. Increased risk for exposure is seen with travel to countries where VHFs are endemic. Those involved with animals (slaughter houses, animal research) and health-care workers are also at risk. There is no racial and sex predilection, but young children have the greatest susceptibility. In the later stages of the illness, the viral loads are quite high. This period carries the highest risk for disease transmission.

There is dysregulation of the innate immune response, although replication of the viruses in target cells and tissues can directly contribute to the pathological manifestations of VHF. Factors that may contribute to this subversion of the host immune response include the rapid infection and impairment of dendritic cells leading to a sudden and enigmatic death of lymphocytes. The virus-infected cells then liberate a variety of inflammatory mediators. These cause an irreversible alteration in the vascular function and integrity and trigger widespread dysfunction of the coagulation mechanisms which is the hallmark of the VHFs.

PATHOLOGY

Widespread necrosis is seen in many organ systems, together with serous effusions and hemorrhages that are so characteristic of these diseases. The liver is extensively involved to extent of massive hepatocellular necrosis and failure. Diffuse alveolar hemorrhage and interstitial pneumonitis occurs in the lungs. The kidney shows features of acute tubular necrosis and microvascular thrombosis.

CLINICAL FEATURES

The illness is characterized by sudden onset of high-grade fevers with myalgia and severe prostration. Bleeding manifestations become evident in the form of petechial hemorrhages in the skin, ecchymoses or a more severe generalized bleeding.

Arenaviruses

The incubation period is 10–14 days. There is a gradual onset of fever with cough and pharyngitis. Vomiting is common. Later, bleeding manifestations and neurological features such as convulsions and coma occur. In newborns, Lassa fever leads to anasarca and shock.

Bunyaviruses

Flu-like symptoms occur but patients recover without complications. The incubation period is 2–6 days. The illness begins with fever, nausea, vomiting and abdominal pain. Hemorrhagic disease occurs in less than 20% cases. Ocular involvement can manifest as retro-orbital pain, retinitis and visual loss. Neurological dysfunction and renal failure occur in the later stages of the illness.

Filoviruses

The incubation period for both Marburg and Ebola viruses is 2–21 days. The disease begins with an acute onset of high-grade fever with headache, myalgia and arthralgia. These symptoms last less than a week. This is followed by a maculopapular rash and hemorrhage. Hepatitis and pancreatitis are quite common. Shock and disseminated intravascular coagulation (DIC) with multiorgan failure occur in severe cases after the second week of illness.

Flaviviruses

The incubation period in the human host is 3–6 days. After the initial viral prodrome, the illness can either resolve spontaneously or undergo remission for a short period and evolve into a fulminant infection. Bleeding diathesis with shock and myocardial dysfunction can occur. Yellow fever virus is hepatotropic and can lead to hepatocellular failure.

DIFFERENTIAL DIAGNOSIS

In the absence of a specific diagnostic test, a high index of clinical suspicion is required to diagnose VHF. They are often difficult to diagnose in the initial few days of the illness because they present with nonspecific viral prodromal features.

Infections that need to be differentiated from a VHF include malaria, meningococcal bacteremia, gram-negative bacteremia, rickettsial infections, influenza, leptospirosis, salmonellosis, Q fever, toxic shock syndrome, hemorrhagic varicella, hemorrhagic measles and septicemic plague. Noninfectious differentials include thrombotic/immune thrombocytopenic purpura, acute leukemia, hemolytic uremic syndrome and various collagen vascular diseases.

DIAGNOSIS

Viral hemorrhagic fever should be considered in any patient with the following clinical presentation in the absence of an alternative diagnosis:

- Acute fever of duration less than 3 weeks in a severely ill patient
- Hemorrhagic manifestations (at least two of the following: petechial rash, epistaxis, hematemesis, hematochezia/malena or any other bleeding)
- No predisposing factors for a bleeding diathesis.

Laboratory findings are nonspecific and include leukopenia (except in Lassa fever), thrombocytopenia, elevated transaminases, increased serum bilirubin, anemia or hemoconcentration, prolonged prothrombin time (PT), activated partial thromboplastin time (APTT) and bleeding time, elevated fibrin degradation products (FDPs), hypofibrinogenemia, proteinuria, hematuria and increased blood urea nitrogen (BUN) and serum creatinine.

Immunological evidence of infection can be obtained by antigen capture testing by enzyme-linked immunosorbent assay (ELISA), and antibody testing in paired sera. Combined antigen and antibody testing has high specificity and sensitivity for early diagnosis of Lassa fever and the results have prognostic value (presence of indirect fluorescent antibody early in disease is associated with high mortality).

Viral isolation in cell culture is currently the gold standard of viral detection; however, this may only be undertaken at a research and biosafety level 4 (BSL-4) facility. Virus can also be detected by polymerase chain reaction (PCR). Clinical specimens in an outbreak

need to be sent to the Centers for Disease Control and Prevention (CDC) or the US Army Medical Research Institute of Infectious Diseases (USAMRIID). Postmortem skin biopsies fixed in formalin and blood collected within a few hours of death by cardiac puncture can be used for diagnosis. Samples should be sent for testing to a reference laboratory with BSL-3 and BSL-4 capability.

MANAGEMENT

The medical management should follow the guidelines in **Table 1**.

Supportive Care

Supportive care includes maintenance of fluid and electrolyte balance and circulatory volume. Mechanical ventilation, dialysis and appropriate therapy for secondary infections may be indicated. Anticoagulant therapy, aspirin, nonsteroidal anti-inflammatory medications and intramuscular injections are contraindicated.

Ribavirin Therapy

Ribavirin is recommended for (1) those with VHF of unknown etiology pending viral identification; and (2) suspect, probable or confirmed cases caused by an arenavirus or bunyavirus. Ribavirin is not recommended for filoviruses and flaviviruses.

PROGNOSIS

Mortality for arenavirus infections ranges from 5% to 35%. Up to one-third of Lassa fever survivors develop sensorineural deafness. Case fatality rate in humans is 1% for RVF and 1–50% for the hantaviruses. Case fatality rate for Marburg hemorrhagic fever ranges from 23% to 70% and 50–90% for Ebola hemorrhagic fever. Complications and sequelae include arthralgia, parotitis, transverse myelitis and pericarditis. Fetal and neonatal infections are associated with high mortality. Infections with yellow fever are usually mild; however, patients may develop severe illness with fulminant hepatitis, coagulopathy and overt bleeding. Case fatality depends on the epidemic but may reach up to 50% in severe cases.

PREVENTION

The CDC and WHO have developed practical hospital-based guidelines *Infection Control for Viral Hemorrhagic Fevers in the African Health Care Setting*. The manual can help health care facilities recognize cases and prevent hospital-based disease transmission with few financial resources. Health care workers

Table 1 Management of viral hemorrhagic fevers

Categorization	Medical management
A. Exposed persons	Medical surveillance. No postexposure prophylaxis is recommended*
B. Suspected VHF case of unknown viral type	Supportive care + Ribavirin** therapy
C. Suspected or confirmed VHF case known to be caused by an flavivirus or filovirus	Supportive care only
D. Suspected confirmed VHF case known to be caused by an arenavirus or bunyavirus	Supportive care + Ribavirin therapy

*A previous CDC recommendations state that ribavirin should be given to high-risk contacts of persons with Lassa fever. The Working Group on Civilian Biodefense recommends medical surveillance only, and notes that the CDC guidelines may be under review.

**Ribavirin therapy should be initiated promptly unless another diagnosis is confirmed or the etiologic agent is known to be a flavivirus or filovirus.

should use standard contact and droplet precautions with eye protection while attending the VHF patients. Prevention should also focus on avoiding contact with vectors in endemic countries. The only licensed vaccine, at present, is available against yellow fever.

IN A NUTSHELL

1. Viral hemorrhagic fevers are caused by four viruses from different families with clinical severity ranging from mild to potentially serious with multisystem involvement.
2. Diagnosis in the initial 3–7 days of illness is difficult since they mimic influenza-like syndromes.
3. Doctors should immediately notify their laboratories and the concerned local health department when VHF is suspected.
4. Virus can only be detected in laboratories equipped with BSL-3 and BSL-4 precautions.
5. There is no established treatment, therefore preventive strategies form the cornerstone of management.
6. The mainstay of management involves hospitalization and supportive care.
7. Survivors might develop disabling complications like deafness, uveitis and postencephalitic sequelae.
8. Preventive efforts should focus on community-wide vector control.
9. Viral hemorrhagic fever viruses can serve as potential weapons for bioterrorism.

Chapter 31.19

HIV and Acquired Immunodeficiency Syndrome

Milind S Tullu, Chhaya Divecha

Human immunodeficiency virus (HIV) infection and acquired immunodeficiency syndrome (AIDS) caused by HIV-1 and HIV-2 viruses has been one of the most devastating infections faced by mankind for the last three decades. Although initially a disease of the so called *high risk population*, this disease has gradually and eventually penetrated upto all sections of the society. Though children form only about 6% of the global HIV burden, they suffer more due to rapid progression with consequent higher mortality. Due to the availability of treatment and better access to antiretroviral therapy (ART), as well as the availability of drugs to treat opportunistic infections (OIs), the (HIV) disease has now been converted to a chronic disorder with longer survival. The HIV infection (besides being a chronic medical disorder), has many social ramifications (particularly in children, due to demise of parents and broken families) and economic adversities. Though the HIV *epidemic* appears to have currently stabilized, it is still an important disease contributing to significant morbidity and mortality in the developing world.

THE PROBLEM STATEMENT

As per the UNAIDS (United Nations Program on HIV/AIDS) report on global AIDS epidemic, 35.3 million people were living with HIV or AIDS in 2012, of which 3.3 million were children less than 15 years of age. In the year 2012, there were 1.6 million deaths due to AIDS-related causes worldwide (around 30% decline from the mortality in 2005). Following the same trend, childhood AIDS related deaths have also reduced from 320,000 in the year 2005 to 210,000 in the year 2012.

Due to scaled-up and improved HIV prevention services, the annual number of newly infected children in the year 2012 was 260,000 in low- and middle-income countries, 35% lower than that in 2009. From 2001 to 2012, there was a 52% decline in new HIV infections among children. In the year 2012, more than 9.7 million people living with HIV were receiving ART in low- and middle-income countries, of which 630,000 are children under 15 years of age. Over the past few years (2009–2012), improved access to healthcare services to prevent mother-to-child transmission has prevented 670,000 children from acquiring HIV infection.

In the *South and Southeast Asia*, 3.9 million people were living with AIDS in 2012, of which 200,000 were children less than 15 years of age. Every year, around 21,000 children are newly infected with HIV, while 13,000 die due to AIDS related causes in this geographical region. There were 0.116 million new HIV infections in adults and 14,500 new HIV infections amongst children in the year 2011. India observed around 0.148 million deaths in 2011 due to AIDS related causes of which 7% were children. Despite a declining trend in the adult HIV prevalence in the high prevalence states in India, there has been a rising trend in many other states in the North, North-East and North-West.

THE VIRUS

Human immunodeficiency virus is a lymphotropic ribonucleic acid (RNA) retrovirus. It belongs to the genus *Lentivirus* and subgroup *Retrovirus*. There are two types, HIV-1 and HIV-2, of which the type HIV-1 is predominant worldwide and the type 2 is concentrated in

West Africa. HIV is further classified into the *major* M group which contributes to more than 90%, *outlier* O group found in Western and Central Africa and *new* N group which was discovered in 1998. The M group shows nine distinct genetic subtypes A, B, C, D, E, G, H, J and K. Subtype C is predominant subtype in the Indian population.

The HIV-1 virus contains two identical strands of HIV-RNA, enzymes and accessory proteins; surrounded by bullet shaped core/capsid. The HIV-1 genome consists of *long terminal repeats* at either ends (which regulate and express the HIV genes) and three major sections in between the GAG region which encodes viral core proteins (e.g., p24), the POL region which encodes viral enzymes (e.g., reverse transcriptase and protease) and the ENV region which encodes viral envelope proteins (e.g., gp120 and gp41). In addition, it also has accessory and regulatory proteins (nef, vif, vpr, etc.) which aid in viral replication. The external glycoprotein gp120 attaches to the CD4 cell receptors by binding to the coreceptors (CCR5 and CXCR4) on the cell surface.

After binding, gp41 is inserted into the CD4 cell, resulting in membrane fusion and fusion with pores. The viral core is released into the CD4 cell cytoplasm and the HIV genome is reverse transcribed to deoxyribonucleic acid (DNA) by the reverse transcriptase. This step being highly error-prone, it can generate mutations or quasispecies, which enables the virus to escape recognition by cellular immunity system. Viral DNA is transported to the nucleus and inserted into the host DNA by viral integrase. This is referred to as *provirus* having the advantage of latency or dormancy for long periods. The translated viral proteins are processed subsequently by viral proteases and assembled into new virions, which on release from the cell, infect other target organs and complete the viral life cycle.

PATHOGENESIS

Human immunodeficiency virus is lymphotropic and selectively binds to CD4 expressing cells, i.e., helper T lymphocytes (CD4 T cells) mainly and the cells of the macrophage-monocyte lineage. Depletion or dysfunction of these cells leads to immunodeficiency. CD4 is also expressed by microglia, astrocytes, oligodendroglia and villus Hofbauer cells (placenta), whose functional impairment also contributes to HIV disease.

On inoculation via mucosal route, the HIV traverses through the submucosa and spreads to draining lymph nodes via infection of CD4+ CCR5+ cells, establishing viral reservoirs. During this initial period of 10 days (*eclipse phase*), the virus cannot be detected in the peripheral blood. The infected CD4 lymphocytes proliferate in the lymphoid tissues leading to generalized lymphadenopathy (*acute retroviral syndrome*). The HIV replication reaches a threshold within the next 3–6 weeks of infection, following which there is a burst of viremia in the plasma characterized by *flu-like* symptoms (fever, rash, lymphadenopathy, arthralgia, etc.). Thereafter, there is decrease in the blood viral loads and subsequent steady state within 6–12 months of primary infection. Children do have higher peaks of viremia and a longer acute phase compared to adults.

Thereafter, the patient enters a clinical phase of latency up to 8–12 years, during which high viral turnover and CD4+ lymphocyte depletion continues. Infected monocytes may act as reservoirs of HIV and effectors of tissue damage. There is slow and progressive decline in the CD4 count (direct viral killing of infected cells, increased apoptosis and killing of infected cells by CD8 cytotoxic lymphocytes), whereby the immunocompromised host is rendered susceptible to various opportunistic infections (OIs). Progression of the disease is related to gradual disruption of lymph nodes with loss of its ability to restrict the virus. During later stages, the virus recirculates following gradual disruption of lymph nodes, producing high level of viremia and a rapid decline of CD4+ T cells.

Older children or those with end stage disease may eventually show lymphopenia.

MODES OF TRANSMISSION

Human immunodeficiency virus infection is transmitted by vertical transfer from mother to child; parenteral exposure to infected blood or blood products (especially in those who undergo multiple blood/blood-product transfusions); needle-sharing by drug abusers (in adolescents); and by unprotected sexual contact (in adolescents and adults).

Most new cases in *pediatric population* are through vertical (mother to child) transmission. This vertical transfer of HIV infection can be during *pregnancy* (in 5–10%), during *labor* (in 10–15%) or due to *breastfeeding* (in 5–20%). Breastfeeding assumes an important route of transmission in developing countries as the risk of transmission increases from 15–25% to 20–35% (with breastfeeding for 6 months) and even up to 30–45% (with prolonged breastfeeding for 18–24 months). The risk of HIV transmission with mixed feeding is even higher.

The *predisposing factors* which increase the risk during vertical transmission are preterm delivery (less than 34 weeks), antenatal low maternal CD4 levels, illicit drug use in pregnancy, ruptured membranes (more than 4 hours), low birth weight, high maternal viral loads and advanced disease in mother. The transmission can be reduced by elective cesarean section and ART to the mother and child.

CLINICAL FEATURES

Human immunodeficiency virus has a broad spectrum of *manifestations* ranging from nonspecific to specific symptoms and signs. It is a multiorgan disease. Children present differently from adults. This is mainly due to their immature and developing immunity, which allows dissemination amongst all the organ systems. Three clinical patterns were described in children [before the introduction of highly active antiretroviral therapy (HAART)]—*rapid, short-term and long-term progressors*. *Rapid progressors* (15–25%) have onset of AIDS within first few months of life and median survival of 6–9 months (if untreated). They are common in HIV-infected newborns in developing countries and present with OIs and neurological manifestations. *Short-term progressors* (60–80%) are seen amongst majority of perinatal infections (mainly intrapartum transmissions). They present with HIV related illness by 3–4 years and progress to AIDS later (by 6–7 years); median survival being 6 years. They commonly present with recurrent bacterial infections, failure to thrive and lymphoid interstitial pneumonitis (LIP). *Long-term progressors* (<5%) have minimal or no disease progression and are amongst few with perinatal infection. Their relatively normal CD4 counts, very low viral loads (for longer than 8 years) and delayed manifestations (median survival of 12–13 years) are probably due to effective humoral immunity, cytotoxic T lymphocytic response, host genetic factors or infection with attenuated/defective virus.

The *clinical presentation* also varies amongst infants, children and adolescents. Infants commonly present with lymphadenopathy, hepatosplenomegaly, recurrent gastrointestinal infections, oral thrush and opportunistic infections like *Pneumocystis jiroveci* pneumonia (PCP), and cytomegalovirus (CMV). Beyond infancy, children may present with growth failure, fever, diarrhea and secondary infections. Older children show growth failure, delayed puberty, mild cognitive dysfunction, cardiomyopathy and idiopathic thrombocytopenic purpura (ITP). An entity of *congenital HIV syndrome* has also been described—consisting of microcephaly, prominent box-like forehead, flattened nasal

bridge, short nose with flattened columella, well-formed triangular philtrum and patulous lips with prominent upper vermillion border.

In comparison to developed countries, resource poor settings differ by the presence of additional problems like malnutrition and recurrent infections, which itself influence progression of the disease. Clinical presentation in developing world is unique as compared to developed nations and measles, tuberculosis, varicella, PCP, acute/persistent/recurrent diarrhea, neurological manifestations, contribute to the morbidity and early mortality.

Various classifications have been used in HIV disease for the baseline assessment of the patient, identification of severity of the illness, and decision regarding treatment and prophylaxis. The commonly used classifications are the *Revised CDC Classification* (1994), the *Immune Classification* (Table 1) and the *WHO Clinical Staging* (revised in 2006) (Box 1). Only the common and important manifestations are mentioned in the Box 1.

Children with HIV are commonly diagnosed with the following clinical presentations—failure to thrive (50–70%), hepatosplenomegaly (40–70%), anemia (40–50%), fever (30–60%), lymphadenopathy (40%), coinfection with tuberculosis (TB) (30–50%), diarrhea (20–30%), candidiasis (20%) and central nervous system (CNS) symptoms (5–15%). The organ specific manifestations are described in Table 2. Of the respiratory manifestations, lymphoid interstitial pneumonitis (LIP) needs special mention and is described here.

Table 1 Revised US Centers for Disease Control and Prevention (CDC) Classification (1994) of human immunodeficiency virus (HIV) in children less than 13 years and immune classification (based on absolute CD4 counts or percentage)

<i>Revised CDC clinical categories of HIV in children <13 years (1994)</i>	<i>Immune classification (Based on absolute CD4 counts/percentage of CD4 cells)</i>
<i>Category N: Not symptomatic</i>	<i>Not significant:</i> <11 months (%): >35 12–35 months (%): >30 36–59 months (%): >25 >5 years (cells/mm ³): >500
<i>Category A: Mildly symptomatic</i> More than two of following (but not of category B/C)—Lymphadenopathy, hepatosplenomegaly, dermatitis, parotitis, recurrent or persistent URI, sinusitis, otitis media.	<i>Mild:</i> <11 months (%): 30–35 12–35 months (%): 25–30 36–59 months (%): 20–25 >5 years (cells/mm ³): 350–499
<i>Category B: Moderately symptomatic</i> Symptoms other than those in A or C—anemia/neutropenia/thrombocytopenia persisting >30 days, candidiasis, cardiomyopathy, CMV (onset before 1 month age), hepatitis, recurrent/chronic diarrhea, etc.	<i>Advanced:</i> <11 months (%): 25–29 12–35 months (%): 20–24 36–59 months (%): 15–19 >5 years (cells/mm ³): 200–349
<i>Category C: Severely symptomatic</i> Multiple recurrent serious bacterial infections, disseminated coccidioidomycosis, extrapulmonary cryptococcosis, encephalopathy, disseminated histoplasmosis, Kaposi's sarcoma, etc.	<i>Severe:</i> <11 months (%): <25 12–35 months (%): <20 36–59 months (%): <15 >5 years (cells/mm ³): <200

Abbreviations: CMV, cytomegalovirus; URI, upper respiratory infection.

BOX 1 World Health Organization (WHO, 2006) clinical staging of human immunodeficiency virus (HIV)/acquired immune deficiency syndrome (AIDS) in children below 15 years

Clinical stage 1: Asymptomatic/persistent generalized lymphadenopathy.
Clinical stage 2 (mild): Unexplained persistent hepatosplenomegaly, recurrent or chronic upper respiratory tract infections, herpes zoster, persistent parotid enlargement, etc.

Clinical stage 3 (advanced): Unexplained moderate malnutrition or wasting, persistent fever, persistent diarrhea, persistent oral candidiasis, unexplained anemia or neutropenia or thrombocytopenia, lymph node- or pulmonary-tuberculosis, recurrent bacterial pneumonia, bronchiectasis, etc.

Clinical stage 4 (severe): Unexplained severe malnutrition or wasting, recurrent severe bacterial infections, *Pneumocystis jiroveci* pneumonia (PCP), extrapulmonary tuberculosis, cytomegalovirus (CMV) organ infection, esophageal or tracheobronchial or lung candidiasis, central nervous system (CNS) toxoplasmosis, HIV encephalopathy or HIV cardiomyopathy or HIV nephropathy, etc.

Lymphoid Interstitial Pneumonitis

Lymphoid interstitial pneumonitis is a noninfectious lymphoproliferative pathology and is seen in up to 30–40% of all respiratory disorders in HIV-infected children. It indicates immunological deficiency due to the HIV disease. There is infiltration of mature CD8 lymphocytes, plasma cells and histiocytes in the interstitial parenchyma of the lung, alveolar septae and lymphatics with pulmonary lymphoid tissue hyperplasia (PLH). The pathogenesis has been attributed to an atypical response by a dysregulated immune system (due to HIV infection) to an inhaled or circulated antigen. The clinical manifestations may range from asymptomatic to severe pulmonary insufficiency. The onset is usually in the 2nd or 3rd year of life and the disease is often insidious and slowly progressive. Clinical presentation may be with cough, fatigue, dyspnea, generalized nonmatted symmetrical lymphadenopathy, bilateral chronic parotid enlargement, clubbing, hepatosplenomegaly, etc. However the course, though variable, is generally benign with prolonged survival. Advanced

stages of disease may show oxygen desaturation with cyanosis. The diagnosis is largely clinical. Chest radiograph consist of diffuse bilateral reticulonodular infiltrates (lower more than upper zones) and mediastinal/hilar lymphadenopathy. Raised serum IgG level (more than 2,500 mg/dL) has strong association with LIP. Confirmation of interstitial pattern and monitoring of the extent and severity of the disease can be done by high-resolution computed tomography (HRCT) of the chest. Lung biopsy establishes definite diagnosis, but is rarely used in pediatric practice. The treatment of LIP consists of systemic corticosteroids (prednisolone at 1–2 mg/kg/day) for severe disease with significant hypoxemia and respiratory insufficiency (given for 2–4 weeks with gradual tapering). In refractory cases, lowest possible steroid dose can be continued for 4–6 months.

OPPORTUNISTIC INFECTIONS

Opportunistic infections are the hallmark manifestations of immunodeficiency disorders like HIV. Children with HIV show a gradual decline in (both humoral and cell mediated) immunity, thereby making them increasingly susceptible to OIs. These OIs can be bacterial, fungal, viral or protozoal. One should be able to prevent, diagnose and treat these infections at the earliest to reduce morbidity and mortality in the HIV infected patients. It is important to have a high index of suspicion for clinical diagnosis of these OIs, as all the diagnostic tests may not be available/affordable in developing countries like India.

Pneumocystis carinii (jiroveci) Pneumonia

It is the most common OI in infants, with a high mortality (which may go up to 35%). By 4 years of age, over 80% of children acquire serum antibodies and manifestations in immunocompetent children may be mild to asymptomatic. The incidence in HIV-infected children is highest in the first year, peaking at about 3–6 months of age. The clinical diagnosis in infancy needs a high index of suspicion. HIV-infected children usually present with an acute tetrad of fever, tachypnea, dyspnea and cough. The second peak incidence of PCP is when the CD4 counts fall to less

Table 2 Organ specific manifestations in children with human immunodeficiency virus (HIV)

Organ system	Manifestations	Etiopathogenesis	Diagnosis and treatment
Respiratory system (Figures 1 and 2)	Recurrent upper and lower respiratory tract infections, invasive sinusitis, mastoiditis, bronchiectasis, etc.	<i>Pneumocystis carinii</i> pneumonia (PCP), <i>S. pneumoniae</i> , <i>H. influenzae</i> , <i>P. aeruginosa</i> , Viruses (CMV), Fungi (<i>Candida</i> , <i>Aspergillus</i> , <i>Histoplasma</i> , <i>Cryptococcus</i>), Tuberculosis, Lymphoid interstitial pneumonitis (LIP)	Specific to organism
Central nervous system Primary involvement (HIV neurotropic) seen in 50–90% of perinatal infections in developing regions	Static encephalopathy (25%) as developmental delay, Progressive encephalopathy as neuroregression, microcephaly, symmetrical motor dysfunction, apathy, spasticity, hyper-reflexia, abnormal plantar reflex, gait abnormalities, loss of language and motor skills, etc. Older children—scholastic backwardness, cognitive deterioration, learning disabilities, behavioral problems, cerebrovascular complications, etc.	HIV virus induced neoplasms secondary to immunodeficiency, OIs (TB, <i>Toxoplasma</i> , CMV, JC virus, HSV, <i>Cryptococcus</i> , etc.), and adverse effects of drugs	Neuroimaging: • Cerebral atrophy • Enlargement of ventricles • Basal ganglia calcifications • Leukomalacia • Early treatment in encephalopathy with highly active antiretroviral therapy (HAART) with drugs with good CNS penetration (zidovudine/stavudine/efavirenz) • Rule out comorbid pathology (OIs/stroke/CNS tumor) in case of focal neurological signs or seizures

Contd...

Organ system	Manifestations	Etiopathogenesis	Diagnosis and treatment
Gastrointestinal and hepatic disease	<p>Oral and esophageal lesions, periodontal disease, salivary gland disease (chronic parotid enlargement in 15%), oral hairy leukoplakia, oral ulcers, recurrent or chronic diarrhea, malabsorption, abdominal pain, dysphagia and failure to thrive.</p> <p>HIV or AIDS enteropathy (Malabsorption due to partial villus atrophy by direct HIV infection of gut).</p> <p>Hepatomegaly</p> <p>Chronic hepatitis, portal hypertension, liver failure</p> <p>Pancreatitis</p>	<p>Bacteria (<i>Salmonella</i>, <i>Campylobacter</i>, <i>Mycobacterium avium</i> intracellulare—MAC, <i>M. tuberculosis</i>), Protozoa (<i>Giardia</i>, <i>Cryptosporidium</i>, <i>Isospora</i>, <i>Microsporidia</i>), Viruses (CMV, herpes simplex virus, rotavirus), or fungi (<i>Candida</i>)</p> <ul style="list-style-type: none"> • Viral replication in reticuloendothelial system • Hepatitis B (with Hepatitis D coinfection) or hepatitis C, CMV and MAC <p>Drug induced (pentamidine, didanosine, lamivudine) or OIs (MAC, CMV, PCP, <i>Cryptosporidium</i>)</p>	<p>Proper nutrition essential in failure to thrive.</p> <p>Serum transaminases fluctuations with/without cholestasis (often drug induced)</p>
Cardiovascular system	<p>Dilated cardiomyopathy, coronary artery disease/arterial hypertension, left ventricular hypertrophy, isolated right ventricular and pulmonary disease, pulmonary hypertension and congestive cardiac failure can occur. Resting sinus tachycardia or sinus arrhythmia, pericardial effusion, cardiac tamponade, conduction disturbances, nonbacterial thrombotic endocarditis, and sudden death may be seen</p>	<p>Prolonged immunosuppression, opportunistic infections (OIs), viral infections, nutritional deficiencies, immune-mediated reactions and adverse effects of drug therapy (zidovudine)</p>	<p>Electrocardiography and echocardiography are helpful in assessing cardiac function. Supportive treatment is required (diuretics, vasodilators and inotropes)</p>
Renal disease	<p>Acute tubular dysfunction with fluid and electrolyte abnormalities and/or renal failure.</p> <p>HIV associated nephropathy (focal and segmental glomerulosclerosis with mesangiopathies, nephrotic syndrome), Immune mediated glomerulopathies (IgA nephropathy, lupus-like etc.)</p> <p>HIV associated thrombotic mesangiopathies</p>	<p>HIV infection of epithelial cells, immune-complex mediated, OIs, hyperviscosity (hyperglobulinemia) or use of nephrotoxic drugs (indinavir causing tubulointerstitial nephritis, acute renal failure and renal calculi)</p>	<p>Treatment is with HAART and angiotensin-converting enzyme inhibitors. Nephrotic syndrome is the most common manifestation of pediatric renal HIV disease. Cases resistant to steroid therapy can be candidates for cyclosporine therapy</p>
Dermatological disorders: Severe, recurrent, persistent and resistant	<p>Exclusive to HIV—oral hairy leukoplakia, bacillary angiomatosis, Kaposi's sarcoma</p> <p>Greater frequency/severe in HIV—Seborrheic dermatitis, severe eczema, psoriasis, drug eruptions, aphthous ulcers, HSV, herpes zoster, molluscum contagiosum, anogenital warts, candidal infections, tinea, onychomycosis, impetigo and scabies</p>	<p>Inflammatory or infectious disorders which are not necessarily unique to HIV infection</p>	<p>The disorders tend to be more disseminated and respond less consistently to conventional therapy</p>
Hematological manifestations	<p>Anemia (20–70%)</p> <p>Leukopenia (seen in one-third, commonly neutropenic)</p> <p>Thrombocytopenia (20%)</p> <p>Thrombosis</p>	<p>Chronic infection, inadequate nutrition (folic acid, vitamin B₁₂ or micronutrient deficiency), autoimmune factors, virus-associated conditions (hemophagocytic syndrome or parvovirus B19 red cell aplasia), Bone marrow suppression or due to adverse effect of drugs (zidovudine).</p> <p>Drugs used for treatment or OI prophylaxis or antiretroviral drugs (zidovudine).</p> <p>It may immunologic (i.e., circulating immune complexes or antiplatelet antibodies), or due to drug toxicity or idiopathic.</p> <p>Hyperviscosity (hypergammaglobulinemia), protein C and protein S deficiency</p>	<p>In low erythropoietin levels, subcutaneous recombinant erythropoietin may be useful.</p> <p>Antineutrophil antibodies are the cause, treatment with intravenous immunoglobulin (IVIg) is useful, subcutaneous granulocyte colony-stimulating factor can be used.</p> <p>Treatment with IVIG or anti-D offers some improvement. If ineffective, a 2–3 days course of high-dose steroids is an alternative. ART can also reverse the thrombocytopenia</p> <p>Clinical disease due to arterial or venous thrombosis rare</p>

Organ system	Manifestations	Etiopathogenesis	Diagnosis and treatment
Malignancies	Non-Hodgkin lymphoma and primary CNS lymphoma Kaposi's sarcoma	Epstein-Barr virus Human herpes virus 8	Chemotherapy and ART
Other organs	HIV—arthropathy, myopathy, rheumatologic, endocrine and metabolic disorders	—	Symptomatic treatment and ART
Growth, nutrition and endocrine system	Growth delay, Delayed puberty, HIV associated lipodystrophy, lipoatrophy, hyperlipidemia, Insulin resistance, hyperinsulinemia, hyperglycemia	Infections, altered gastrointestinal and metabolic functions, drugs, antiretroviral medications, malnutrition	Nutritional assessment in all patients, counseling and education, 1–5 times recommended intake of vitamins and minerals, oral supplements/enteral tube feedings/parenteral nutrition

Abbreviations: PCP, *Pneumocystis carinii* pneumonia; CMV, cytomegalovirus; LIP, lymphoid interstitial pneumonitis; TB, tuberculosis; HSV, herpes simplex virus; HAART, highly active antiretroviral therapy; CNS, central nervous system; OI, opportunistic infection; MAC, *Mycobacterium avium* intracellulare, IVIG, intravenous immunoglobulin.

Figure 1 High-resolution computed tomography (HRCT) chest showing bilateral bronchiectatic changes in a human immunodeficiency virus (HIV) infected child

Figure 2 Chest radiograph showing bilateral extensive lobar consolidation (pneumonia) in a human immunodeficiency virus (HIV) infected child

Figure 3 Chest radiograph of *Pneumocystis jirovecii* pneumonia (PCP) showing bilateral diffuse parenchymal infiltrates

than 200 cells/mm³ or less than 14% due to new infection or an activation of a latent infection. Insidious onset cough and dyspnea may be seen in older children. Clinical features and differential

diagnoses of PCP are discussed in Chapter 33.9 on *Pneumocystis jirovecii* (**Fig. 3**). *P. carinii* (*jirovecii*) can be demonstrated from induced sputum samples (50% sensitivity; 90% specificity) or less commonly in bronchoalveolar lavage (BAL) samples (90% sensitivity; 99% specificity even at 72 hours after treatment initiation), fiberoptic bronchoscopy with transbronchial biopsy (if BAL is negative) and open lung biopsy. PCP is treated with IV trimethoprim-sulfamethoxazole; steroids are given in severe cases (See Chapter 33.9 for details of treatment of PCP). If child does not improve within 4–7 days, it is prudent to consider other etiologies, coinfections (with other organisms like pneumococcus or CMV) and treatment failure. Surfactant therapy may be considered as last option in severely ill infants. Cotrimoxazole (TMP-SMX) prophylaxis reduces the incidence of PCP infection (dose: 6 mg/kg/day of TMP). TMP-SMX also protects against development of infections by other bacteria, malaria, *Isospora*, *Cyclospora* as well as toxoplasmosis, besides reducing the mortality in children. The 2009 WHO Guidelines for cotrimoxazole use are described in **Table 3**.

Tuberculosis

Human immunodeficiency virus infected children are at a high risk of TB with up to 48% having culture proven TB. The disease tends to be more severe, extrapulmonary, drug resistant and

Table 3 The 2009 World Health Organization (WHO) guidelines for cotrimoxazole for *Pneumocystis carinii* pneumonia (PCP) prophylaxis in children

<i>All HIV exposed infants</i>	Start 4–6 weeks of age after birth and continued for at least 6 weeks after cessation of risk of HIV transmission (breastfeeding) and definitive exclusion of HIV infection in infant	Once a child is started on cotrimoxazole, prophylaxis should be continued until 5 years of age regardless of clinical symptoms or CD4 percentage. Specifically, infants who begin cotrimoxazole prophylaxis before the age of 1 year and are subsequently asymptomatic and/or have CD4 levels >25% should remain on cotrimoxazole prophylaxis until they reach the age of 5 years
<i>HIV-infected children</i>		
<1 year	Used in all, regardless of CD4 percentage or clinical status	
1–4 years	Prophylaxis required if the child has WHO clinical stages 2, 3 or 4, regardless of CD4 percentage or if the child has CD4 percentage below 25% at any WHO stage	
>5 years	WHO clinical stage 2, 3 and 4 (if CD4 counts are not available) or WHO clinical stage 3 and 4 (irrespective of CD4 counts) or if CD4 count <350 cells/mm ³ irrespective of WHO staging	Children older than 5 years can be reassessed and consideration given to discontinuing cotrimoxazole prophylaxis after sustained immune reconstitution in accordance with the recommendations for adults and adolescents
OR		
<i>Universal option:</i> Prophylaxis for all infants and children born to mothers confirmed to be or suspected of living with HIV. This strategy may be considered in settings with a high prevalence of HIV, high infant mortality due to infectious diseases and limited health infrastructure.		
<i>Previous infection with PCP</i>	Secondary cotrimoxazole prophylaxis has the same regimen as recommended for primary prophylaxis	The general recommendation is that secondary cotrimoxazole prophylaxis should not be discontinued, irrespective of the clinical and immune response to ART

Abbreviations: PCP, *Pneumocystis carinii* pneumonia; HIV, human immunodeficiency virus; ART, antiretroviral therapy.

associated with atypical mycobacteria. Younger children present commonly with localized pulmonary involvement with hilar adenopathy, extrapulmonary and miliary TB, while older children and adolescents may show cavitary TB. Drug sensitivity testing should be done in positive cultures especially in treatment failures and relapses. Antitubercular therapy (ATT) should be started as per standard guidelines with prolongation of the course if needed. ART should be started in any child with active disease as soon as possible and within 8 weeks following initiation of antituberculous treatment irrespective of CD4 count and clinical stage. It should be remembered that rifampicin induces increased hepatic clearance of protease inhibitors (PIs) and non-nucleoside reverse transcriptase inhibitors (NNRTIs). The concomitant use of rifampicin with efavirenz and nevirapine also requires dose adjustments. Children living with HIV should regularly be screened for symptoms of poor weight gain, fever or current cough or contact history with a TB case. If they are more than 12 months old, 6 months of isoniazid preventive therapy (IPT) at 10 mg/kg/day should be given as part of comprehensive package of HIV prevention and care services if they are unlikely to have active TB on screening and have no TB contact. In HIV-infected children less than 12 months of age, IPT should be offered to only those with contact with TB case if evaluation (using investigations) shows no TB disease.

Recurrent Bacterial Infections

Common bacterial infections seen in HIV-infected children are pneumonia, sepsis, bacteremia, abscesses, meningitis, osteomyelitis, septic arthritis, otitis media, etc. These are caused by organisms like *Streptococcus pneumoniae*, *Haemophilus influenzae* type *b* (Hib), *Staphylococcus aureus*, *Escherichia coli*, *Pneumococcus*, etc. The clinical presentation and treatment is essentially similar to that in the non-HIV infected children; however the disease may be chronic/severe and longer duration of antibiotics may be necessary. Prophylaxis with TMP-SMX, routine as well as special vaccinations (pneumococcal and Hib vaccines) and screening can reduce the incidence of bacterial infections.

Mycobacterium avium Complex (MAC)

These are non-tuberculous mycobacteria [i.e., *M. avium* (predominantly a disseminated disease), *M. intracellulare* (predominantly

respiratory manifestations) and *M. paratuberculosis*] and are seen frequently in children with low CD4 counts (less than 50 cells/mm³), high plasma HIV-RNA levels (more than 100,000 copies/mL), previous OIs and previous colonization of the respiratory and gastrointestinal tract. MAC can present as isolated lymphadenitis or with involvement of lungs, liver, spleen, bone marrow and gastrointestinal tract. Disseminated MAC infection usually presents in children with advanced HIV disease. Common presentations are—recurrent fever, failure to thrive, night sweats, fatigue, chronic diarrhea and recurrent abdominal pain. The diagnosis is by isolation or culture of organism from blood or biopsy specimen. DNA probe assays can be used for species differentiation. Associated laboratory findings such as anemia (disproportionate to stage of HIV), neutropenia, leukopenia and elevated serum alkaline phosphatase may also be seen. The treatment includes a combination of two or more drugs and therapy is recommended for at least 18 months. Clarithromycin (7.5–10 mg/kg/day PO BD) or azithromycin (10–12 mg/kg/day PO OD) with ethambutol (15–20 mg/kg/day PO OD) can be used. Alternative drugs are ciprofloxacin, amikacin or streptomycin. Disseminated disease requires 3–4 drugs combination to be given till there is improvement followed by two drug therapy. Primary prophylaxis with clarithromycin or azithromycin is required when the CD4 count is less than 50 cells/mm³ in children more than 6 years age, less than 75 cells/mm³ in 1–6 year age group and less than 500 cells/mm³ in less than 1 year of age. Secondary prophylaxis with clarithromycin (or azithromycin) and ethambutol is recommended in diagnosed cases of MAC.

Candidiasis

Candida is the most common fungal infection in HIV-infected children. Oral thrush is most common and recurrent presentation is one of the clinical indicators of HIV in infants more than 8 weeks of age. Esophageal candidiasis is an AIDS-defining condition with increased occurrence in patients with low CD4 counts (less than 100 cells/mm³), high viral load, neutropenia and concomitant oropharyngeal candidiasis. Systemic candidiasis may occur with prolonged use of antibiotics and can also manifest as endophthalmitis, shock or sepsis (also see Chapter 33.3 on Candidiasis). The treatment of oral thrush is topical clotrimazole

(4–6 hourly for 1–2 weeks) or oral nystatin suspension. Oral fluconazole, itraconazole or ketaconazole can be used if topical therapy fails. For esophageal candidiasis, the treatment is with intravenous fluconazole (3–6 mg/kg/day for 21 days) which can be made oral once child can swallow food. For treatment of systemic candidiasis, amphotericin B (0.5–1.5 mg/kg OD IV over 1–2 hours) has to be given for 14–21 days (after resolution of signs

and symptoms and last positive blood culture). Flucytosine can be added in severe invasive disease. *Prophylaxis* is recommended with fluconazole (3–6 mg/kg PO OD) or itraconazole (5 mg/kg PO OD) in cases with severe mucocutaneous or esophageal candidiasis and can be stopped once the CD4% is more than 15% on more than two occasions (on ART). **Table 4** summarizes the OIs seen in HIV-infected children.

Table 4 Opportunistic infections (OIs) in children with human immunodeficiency virus (HIV)

<i>Infection/pathogen</i>	<i>Clinical findings/organ involvement</i>	<i>Diagnosis</i>	<i>Treatment and prophylaxis</i>
Cytomegalovirus (CMV): 8–10% of pediatric AIDS defining illness	<i>CMV retinitis</i> : Most common, usually asymptomatic. Lungs, liver, GI tract, pancreas, sinuses and CNS	<i>Fundoscopy</i> : White and yellow retinal infiltrates and retinal hemorrhages. <i>Histology</i> : Owl eye intranuclear and intracytoplasmic inclusion bodies. Staining with CMV monoclonal antibodies. <i>Serology</i> : Not very useful but negative IgG makes CMV disease unlikely. <i>CMV—Antigenemia (acute or latent infection)</i> : Viral matrix protein pp65 on infected neutrophils. Viral cultures, CMV DNA PCR.	Ganciclovir for 14–21 days or foscarnet followed by lifelong maintenance therapy with ganciclovir. Fundoscopy every 6 monthly in all HIV children. <i>Prophylaxis</i> : Primary-Ganciclovir in HIV children with severe immunosuppression (CD4 <50 cells/mm ³). Secondary-Ganciclovir.
HSV (Herpes simplex virus) Vertical or horizontal transmission. *HSV ulcers >1 month VZV (Varicella/Herpes Zoster virus)	Neonatal (usually HSV2): CNS, skin, eyes or mouth. Beyond neonatal age: Extensive orolabial ulcers (gingivostomatitis), genital ulcers, encephalitis or systemic disease. Severe infection, mucosal involvement, systemic spread: pneumonia, hepatitis, encephalitis, retinitis.	Ulcers are clinically diagnostic. Virus isolation in culture, immunofluorescence staining of HSV 1 and HSV2 antigens from skin and mucosal scrapings, detection of HSV DNA by PCR in CSF in HSV encephalitis. Tzanck smear from cell scrapings, VZV antigen in lesions, Viral isolation from culture, PCR.	Acyclovir. Neonatal CNS disease—21 days. Other involvement in neonates, post neonatal CNS, gingivostomatitis: 14 days. <i>Prophylaxis</i> : Not recommended. Prevent exposure. Isolation and oral or intravenous acyclovir for 7–14 days. Intravenous foscarnet in resistant cases. Prophylaxis-Varicella immunoglobulin within 96 hours of exposure.
Toxoplasmosis	Most asymptomatic, CNS toxoplasmosis often with ocular involvement.	Neuroimaging (Fig. 4): Ring-enhancing lesions in basal ganglia, corticomedullary junction, granulomas, calcification. CSF IgG antibodies.	Pyrimethamine-Sulfadiazine with folinic acid. Alternative-clindamycin, azithromycin, or TMP-SMX. Steroids if severe chorioretinitis or CNS involvement with mass effect. <i>Prophylaxis</i> : Primary-TMP-SMX used for PCP prophylaxis protects. Secondary-Sulfadiazine (or clindamycin)-pyrimethamine with folinic acid. Avoid exposure to cat feces, proper hand washing and avoid uncooked or raw meat ingestion.
<i>Cryptococcus neoformans</i>	Meningitis is most common. Others—bones, joints, skin, lungs. Severely immunocompromised children between 6 years and 12 years are more prone.	CSF examination—may be normal, but elevated opening pressure, India ink preparation, cultures, cryptococcal antigen (useful for response to treatment).	<i>Induction</i> : Amphotericin B with/without flucytosine for 2 weeks. <i>Consolidation</i> : Fluconazole for 8–10 weeks or Itraconazole for 2 weeks. <i>Prophylaxis (only secondary)</i> : fluconazole lifelong or till CD4 improves to 100–200 cells/mm ³ (adolescents on ART).
Histoplasmosis	Acute pneumonia, meningitis Progressive disseminated histoplasmosis (in CD4 ≤150 cells/mm ³) presents with prolonged fever, failure to thrive, pneumonitis, hepatosplenomegaly, lymphadenopathy.	Cultures, histopathology, serology, antigen detection (serum, BAL, CSF with 100% sensitivity), PCR.	Amphotericin B Secondary prophylaxis-oral itraconazole for 1 year.

Contd...

Contd...

Infection/pathogen	Clinical findings/organ involvement	Diagnosis	Treatment and prophylaxis
Penicilliosis* Seen in North–East India	Persistent fever, anemia, thrombocytopenia, skin lesions (translucent umbilicated papules–face, ears, extremities), hepatomegaly, generalized lymphadenopathy.	Wright staining of skin scrapings–basophilic, spherical yeast like with central septation. Isolation from blood, bone marrow, etc.	Amphotericin B intravenous for 2 weeks followed by oral itraconazole for 10 weeks. Secondary prophylaxis (only)–Itraconazole.
<i>Isospora belli</i> and <i>Cyclospora</i>	Chronic diarrhea	Stool microscopy, antigen detection	TMP-SMX
<i>Microsporidia</i>	Chronic diarrhea	Stool microscopy, antigen detection	Albendazole or Nitazoxanide
<i>Cryptosporidia</i>	Acute or persistent diarrhea. Complications–cholecystitis, cholangitis, hepatitis, pancreatitis, severe malabsorption	Stool microscopy, staining and antibody detection	Fluid rehydration. Nitazoxanide or Azithromycin

Abbreviations: HSV, herpes simplex virus; PCR, polymerase chain reaction; CSF, cerebrospinal fluid; CNS, central nervous system; VZV, Varicella/Herpes Zoster virus; CMV, cytomegalovirus; TMP-SMX, trimethoprim-Sulfamethoxazole; ART, antiretroviral therapy; BAL, bronchoalveolar lavage.

*AIDS defining illness

Figure 4 Magnetic resonance imaging (MRI) brain of toxoplasmosis showing well defined peripherally enhancing lesion with surrounding perilesional edema in right gangliocapsular region with mass effect

DIAGNOSIS OF HIV INFECTION

It can be done by virological or serological methods (if more than 18 months age). Presumptive diagnosis can also be made by certain clinical criteria in children less than 18 months where virological methods are unavailable. These methods are further described in **Table 5**. The WHO recommendations are summarized in **Table 6**.

MANAGEMENT OF HIV INFECTION

The management of HIV disease has changed dramatically after the availability of effective ART. ART cannot cure HIV infection but it helps in achieving an acceptable quality of life, normal growth and development and minimizes morbidity due to OIs and organ involvement. Antiretroviral regimens available now-a-days are safer, simpler to follow, efficacious and affordable than before. ARTs are potent inhibitors of viral replication, which by reducing viral burden; make the disease a chronic illness. ART should be administered under the guidance of an expert in pediatric HIV disease. The basics of ART are summarized in **Tables 7** and **8**. The indications for starting ART and WHO first-line regimen is

described in **Table 9** while other general aspects of health-care and management in children with HIV infection are summarized later.

Monitoring

All HIV patients (with/without ART) should undergo clinical and laboratory monitoring for disease activity and response to treatment. Complete hemogram, liver functions, urine and stool examination, fundoscopy, echocardiography (ECG) and height should be monitored annually and CD4 counts every 3–6 monthly. At each visit healthcare provider should assess immunization status, symptoms of OIs, cotrimoxazole prophylaxis and concomitant medications and also reassess criteria for ART initiation and evaluate the family situation. While patients on ART should be followed-up monthly, those children not on ART also require regular follow-up.

Counseling

Children of school age should be disclosed their HIV-positive status and their parents or caregiver's status; younger children should be told their status incrementally to accommodate their cognitive skills and emotional maturity (in preparation for a full disclosure). Parents or caretakers should be counseled about the disease and course of the illness. Treatment decisions should be based on adherence, which depends on understanding by caretaker, availability of medicines and accessibility to healthcare and socioeconomic conditions.

Prophylactic Regimens

Pneumocystis carinii (*jiroveci*) pneumonia prophylaxis has already been discussed. Prophylaxis against MAC is required in children with severe immunosuppression (i.e., CD4 lymphocyte count < 500 cells/mm³ in children < 1 year, < 75 cells/mm³ in 1–6 years age, and < 50 cells/mm³ in children > 6 years age) and the drugs of choice are clarithromycin (7.5 mg/kg twice a day orally) or azithromycin (20 mg/kg once a week orally or 5 mg/kg daily orally). Primary prophylaxis against OIs can be discontinued if patients have sustained (> 6 months) immune reconstitution with HAART. Intravenous immunoglobulin (IVIG) (dose 400 mg/kg every 4 weeks) has been recommended to prevent recurrent serious bacterial infections for symptomatic patients who have suffered from at least two documented serious bacterial infections within 1 year; have laboratory-documented inability to make antigen-specific antibodies; or in those who have hypogammaglobulinemia.

Table 5 Diagnosis of human immunodeficiency virus (HIV) in children

Serological tests: <ul style="list-style-type: none">• Detect HIV antibodies• Enzyme immunoassays (EIA), rapid tests, Western Blot• Whole blood, oral fluids (less common)• Passive transfer of maternal IgG HIV antibodies usually disappear by 6–12 months in infants (seroreverters)• Diagnosis established only in infants >18 months of age• If 1st test reactive, diagnosis to be confirmed by 2nd (or 3rd in high prevalence regions) test using different method		Virological tests: Include HIV RNA/DNA by nucleic acid testing-(NAT) or polymerase chain reaction (PCR) and viral proteins (p24). Useful for definitive diagnosis by 1–6 months of age. At 4–6 months of age, the HIV culture or PCR can identify all infected infants. <i>HIV-DNA:</i> Qualitative test: Diagnostic purposes. On whole blood/dried blood spot (DBS). HIV-DNA PCR: About 40% of infected newborns have positive test results in the first 2 days of life, with more than 90% testing positive by 2 weeks of age. <i>HIV-RNA:</i> Quantitative test: Monitoring disease progression and response to ART. On plasma or DBS. <i>Ultrasensitive p24:</i> Enzyme linked immunoassays (EIA). On whole blood/serum.	
Presumptive diagnosis in <18 months of age (where virological testing unavailable): Presumptive diagnosis of severe HIV disease if: HIV antibody positive confirmed			
AND			
Two or more of following: <ul style="list-style-type: none">• Oral thrush• Severe pneumonia• Severe sepsis <i>Other supportive factors for diagnosis:</i> <ul style="list-style-type: none">• HIV-related maternal death• Advanced HIV disease in mother• CD4 count (child) <20%		OR	Diagnosis of AIDS indicator condition(s): Pneumocystis pneumonia, cryptococcal meningitis, severe wasting or severe malnutrition, esophageal candidiasis, Kaposi sarcoma, extrapulmonary tuberculosis
<i>Diagnosis of HIV infection should be confirmed by virological testing as early as possible.</i>			
Testing protocols			
<i>At Birth and early infancy:</i> Viral diagnostic assay should be done within 48 hours of birth. If negative at 2 days in HIV exposed child, repeat tests at 1–2 months and 4–6 months of age. Diagnosis of HIV infection by two positive virological tests from different blood samples. Exclusion of HIV infection by two negative virological tests (with at least one test performed at or after 4–6 months of age).			
<i>Older children:</i> Diagnosis by positive ELISA antibody test, confirmation by Western Blot or repeat ELISA with different kit. In those > 18 months of age, ELISA test has > 99% sensitivity and specificity. In developing regions, 2–3 ELISA tests using different kits can be used to confirm positive report. HIV infection excluded if two or more HIV antibody tests are negative 1 month apart after 6 months of age (excluding patients with hypogammaglobulinemia or clinical HIV disease). If breastfeeding: Repeat antibody test should be negative after 6–8 weeks of complete cessation of breastfeeding to confirm absence of infection.			

Table 6 Summary of recommended testing approaches for infants and children [World Health Organization (WHO)]

<i>WHO Recommendations</i>		
Virological testing preferred in all children < 18 months		
HIV exposed infant (well)	HIV DNA/RNA or ultrasensitive p24	To be performed at 4–6 weeks of age or earliest opportunity thereafter. If positive start ART at earliest and confirm with second specimen
Infant with unknown exposure	Maternal or infant HIV serological test	If exposed—virological test
HIV exposed infant at 9 months (well)	HIV serological test	If seropositive: Confirm with virological test. To repeat if negative and breastfeeding.
Infant/child with signs/symptoms suggesting HIV	HIV serological test	If seropositive: Confirm with virological tests if < 18 months age
On discontinuation of breastfeeding	HIV serological test after 6 weeks or more of breastfeeding cessation	If seropositive: Confirm with virological tests if < 18 months
Child > 18 months	HIV serological test	—

Immunization

These are equally important to prevent infections. An asymptomatic child with mild symptoms should be given all routine vaccinations. In case of symptomatic patients with severe

immunosuppression/AIDS, live vaccines [like varicella/measles-mumps-rubella (MMR)] are contraindicated. Inactivated or killed vaccines preferred to live vaccines (e.g., inactivated polio vaccine instead of oral polio vaccine). Vaccines like Hib, annual influenza

Table 7 Fundamental principles of antiretroviral therapy (ART) in children

Principles	<ul style="list-style-type: none"> • Stabilize OIs before starting ART • Aim to suppress HIV replication to undetectable levels—to minimize selection of antiretroviral-resistant mutants. • Use combination therapy of antiretroviral drugs (ARVs) and strict adherence.
Appropriate drug selection	<ul style="list-style-type: none"> • Three main types of ART drugs (based on mechanism of action): <ul style="list-style-type: none"> – NRTIs (nucleoside reverse transcriptase inhibitors) – NNRTIs (nonnucleoside reverse transcriptase inhibitors) – PIs (protease inhibitors) • Highly active antiretroviral therapy (HAART) refers to a three drug combination <ul style="list-style-type: none"> – Two NRTIs (thymidine analog AZT/ZDV plus nonthymidine analog 3TC) suppress replication in active plus resting cells PLUS – One NNRTI (EFV/NVP) or PI (LPVr or NFV)
Adherence	<ul style="list-style-type: none"> • Deciding factor for initiation of ART and its success • Compliance below 80–90% leads to suboptimal viral suppression and enhances development of drug resistance (particularly with PIs and NNRTIs) • Participation and extreme dedication of family/caretaker essential as medications often unpalatable • Education on drug administration, follow-up visits, relationship of drug adherence to viral suppression and commitment of the family and the child are important in achieving treatment success
Initiation of ART	<ul style="list-style-type: none"> • Though ART is lifelong, the first 6 months are most important. This is due to the need to balance the improvement (clinical, immunological and viral suppression) as against the higher risks of opportunistic infections, IRIS, and early adverse events (especially in first 3 months) • People with advanced HIV disease (severe immunodeficiency and existing coinfections), severely low hemoglobin, low body mass index and very low CD4 counts or severe malnourishment are more prone to complications when initiated on ART
Immune reconstitution inflammatory syndrome (IRIS)	<ul style="list-style-type: none"> • IRIS is a collection of signs and symptoms associated with immune recovery due to response to ART • It can occur in up to 10% of all patients initiated on ART or up to 25% in those with CD4 count below 50 cells/mm³ • Typically within the first few weeks (2–12 weeks) after initiation of ART (but may also present later) • It may present as paradoxical IRIS, when an opportunistic infection or tumor diagnosed is before ART and responsive to therapy after ART starts; or unmasking IRIS, in which a disease not clinically apparent before ART is triggered by ART initiation • To be considered when the presentation cannot be explained by a new infection, expected course of a known infection or drug toxicity • Clinical spectrum is diverse—fever, new events, clinical deterioration of OIs • IRIS may be reported for infectious, non-infectious conditions and tumors • The most serious and life-threatening forms of paradoxical IRIS are TB, cryptococcosis, Kaposi's sarcoma and herpes zoster. Worsening of coexisting infections (flare of Hepatitis B or C) may be seen localized or systemic BCG vaccine-associated IRIS may be seen in HIV infected infants • Risk factors for IRIS include low CD4 + cell count (<50 cells/mm³) at ART initiation, disseminated opportunistic infections or tumors and a shorter treatment duration for OIs before starting ART • IRIS is generally self-limiting, and interruption of ART is rarely indicated. Reassurance is essential to prevent discontinuation or poor adherence to ART • Life-threatening reactions may require suppression of exaggerated inflammatory response by short course of corticosteroids. Prednisolone 0.5–1 mg/kg/day for 5–10 days can be added in moderate to severe cases • Measures such as early diagnosis of HIV and initiation of ART before CD4 falls below 200 cells/mm³, improved screening of OIs (especially TB and Cryptococcus) and optimal management before initiating ART can help to reduce development of IRIS
Monitoring ART	<p>HIV Diagnosis:</p> <ul style="list-style-type: none"> • HIV serology, CD4 count, TB screening • Optional: HBV and HCV serology, screening for STIs and noncommunicable diseases and comorbidities <p>Follow-up (Before ART):</p> <ul style="list-style-type: none"> • CD4 count (6–12 monthly) <p>ART initiation:</p> <ul style="list-style-type: none"> • CD4 count • Optional: Hemoglobin (for AZT), pregnancy test (adolescents), blood pressure, urine dipsticks for glycosuria, estimated glomerular filtration rate and serum creatinine (for TDF) and alanine transaminase (for NVP) <p>On ART:</p> <ul style="list-style-type: none"> • CD4 count (6 monthly) • HIV viral load (6 months after start of ART and 12 monthly thereafter) • Optional: Urine dipstick for glycosuria and serum creatinine (for TDF) <p>Treatment failure:</p> <ul style="list-style-type: none"> • CD4 count, HIV viral load • Optional: HBV serology

Contd...

Routine follow-up	<ul style="list-style-type: none">• Review interim history for TB exposure• Assess growth and nutrition• Symptom directed clinical examination• Developmental assessment• Review for concomitant conditions: OIs, TB, etc.• Confirm stage of HIV• Check adherence to treatment• Recalculate ART doses on each visit• Review drug interactions, preventive drugs (Cotrimoxazole, INH)• Discuss findings on each visit• Appropriate referrals• Reinforce ART adherence, nutrition, side effects of drugs, follow-up, etc.• Laboratory tests when needed• Schedule follow up depending on response to ART• Infants: weeks 2, 4, 6, 8 (after starting ART), then every 4 weeks for 1st year• Children: weeks 2, 4, 8, 12 (after starting ART) then 2–3 monthly when child stabilized on ART	
ARV toxicity	<ul style="list-style-type: none">• Rule out concurrent medications and diseases (OIs, IRIS, etc.).	
Adverse reaction based on:	<ul style="list-style-type: none">• Determine seriousness of adverse event:<ul style="list-style-type: none">– Grade 1 (mild): Reassure, no change in ART– Grade 2 (moderate): Continue ART as long as feasible, SOS single drug substitution if no improvement. Stress need to adhere to ART inspite of toxicity in mild/moderate reactions– Grade 3 (severe): Substitute one offending drug, continue rest ART– Grade 4 (severe life-threatening, e.g., Stevens-Johnson syndrome, lactic acidosis, etc.): Immediate discontinuation of all drugs and manage the event. Once patient stabilized reintroduce modified regimen substituting the offending drug	
<ul style="list-style-type: none">• Report of child on ART or caregiver• History or clinical findings• Laboratory tests		
Treatment failure (WHO definitions for decision to switch ART regimens)	Virological failure: (preferred monitoring approach to diagnose and confirm ARV treatment failure). Plasma viral loads (PVL) above 1,000 copies/mL based on two consecutive viral load measurements after 3 months, with adherence support Clinical Failure: New or recurrent clinical event indicating advanced or severe immunodeficiency (WHO clinical stage 3 and 4 except TB) after 6 months of effective treatment Immunological failure: In < 5-year-old: Persistent CD4 levels below 200 cells/mm ³ or < 10% In > 5-year-old: Persistent CD4 levels below 100 cells/mm ³	
Change of ART (due to failure or in toxicity or intolerance to current treatment)		
All drugs to be changed ideally, if not possible at least two drug changed based on resistance mutation genotype or previous ART regimen		
	<i>Preferred regimens</i>	<i>Alternative regimens</i>
If a NNRTI based first-line regimen was used	Boosted PI + 2 NRTIs ABC + 3TC + LPV/r* *ATV/r alternative if > 6 years	ABC + 3TC + LPV/r* TDF + 3TC (or FTC) + LPV/r*
If a PI based first line regimen was used	< 3 years No change unless failure due to lack of adherence due to poor palatability of LPV/r 3 years to < 10 years NNRTI (EFV preferred)+ 3NRTIs AZT (or ABC) + 3TC + EFV	AZT (or ABC) + 3TC + NVP ABC (or TDF) + 3TC + NVP
Adolescents(> 10 years)		
If d4T /AZT used in first-line ART	TDF + 3TC (or FTC) + ATV/r or LPV/r	
If TDF used in first-line ART	AZT + 3TC + ATV/r or LPV/r	
Third-line ART: <ul style="list-style-type: none">• Need to balance benefits versus risks when second line ART fails• Older children and adolescents: use of novel drugs like ETV, DRV and RAL (used in adults) to construct third-line regimen• If not possible, continue tolerated second-line regimen• If ART stopped, symptomatic and pain relief with prevention of OIs		
Resistance	<ul style="list-style-type: none">• Suspected when multiple failed regimen or suboptimal viral load response to therapy• Drug resistance tests measure virus susceptibility in various drug concentrations (phenotype tests) or predicts by mutations identified in HIV genome isolated in patient (genotype tests)• Single mutation can induce high grade resistance in NNRTIs and 3TC• Serial accumulation of multiple mutations required in AZT, ABC, TDF and most PIs• Low level of resistance in ddl and d4T• Drug resistance testing is becoming standard of care and higher treatment success has been noted	
Drug interactions	Amongst antiretrovirals: ZDV and d4T NOT given together ddl and d4T NOT given together EFV NOT with NVP or 3TC	With others: Rifampicin reduces levels of NNRTIs and PIs Antifungals increase levels of NVP, LPV and SQV (sequinavir). Interactions exist with oral contraceptives, lipid lowering agents and anticonvulsants

Abbreviations: OI, opportunistic infections; ART, antiretroviral therapy; BCG, Bacillus Calmette-Guérin (BCG) vaccine; HBV, hepatitis B virus; HCV, hepatitis C virus; INH, isoniazid, PVL, plasma viral loads; AZT/ZDV, zidovudine; NFV, nelfinavir; RTV, ritonavir; ABC, abacavir; ddI, didanosine; FTC, emtricitabine, 3TC, lamivudine, d4T, stavudine, TDF, tenofovir; EFV, efavirenz; ETV, etravirine; NVP, nevirapine; PIs, proteases inhibitors; ATV/r, Atazanavir + ritonavir; DRV, darunavir; LPV/r, lopinavir/ritonavir; RAL, raltegravir.

Table 8 Antiretroviral (ARV) drugs, dosages, adverse effects and substitutions

<i>Antiretroviral drug (class)</i>	<i>Elimination</i>	<i>Formulation</i>	<i>Daily dose</i>	<i>Adverse effects</i>	<i>Suggested first-line ARV substitute</i>
Lamivudine (3TC) (NRTI)	Renal excretion	Oral, syrup available	8 mg/kg in two divided doses	Gastrointestinal symptoms, rash, lactic acidosis, pancreatitis, peripheral neuropathy	—
Zidovudine (AZT/ZDV) (NRTI)	Hepatic metabolism with renal excretion	Oral, syrup available	8 mg/kg or 480 mg/m ² in two divided doses	Severe anemia, leukopenia, pancytopenia, myopathy, lipodystrophy, lactic acidosis or severe hepatomegaly with steatosis Severe gastrointestinal intolerance Headache, liver toxicity	TDF or ABC d4T or ABC
Stavudine (d4T) (NRTI)	50% renal excretion	Oral	2 mg/kg in two divided doses	Lactic acidosis or severe hepatomegaly with steatosis, lipodystrophy, peripheral neuropathy, pancreatitis Headache, nausea, anemia, rash	TDF or AZT or ABC —
Didanosine (ddI) (NRTI)	50% renal excretion	Oral	240 mg/m ² in two divided doses	Gastrointestinal symptoms, peripheral neuropathy, pancreatitis, lactic acidosis	—
Abacavir (ABC) (NRTI)	Hepatic	Oral	16 mg/kg in two divided doses	Hypersensitivity reaction Gastrointestinal symptoms, rash, lactic acidosis, elevated triglycerides, lipodystrophy, pancreatitis	AZT (or TDF or d4T) —
Efavirenz (EFV) (NNRTI)	Hepatic	Oral, syrup available	15 mg/kg (200–400 mg) once a day	Persistent and severe central nervous system toxicity, hepatotoxicity, convulsions, hypersensitivity reactions, potential teratogenicity	NVP If NNRTIs not tolerated-boosted PIs
Nevirapine (NVP) (NNRTI)	Hepatic	Oral, syrup available	120 mg/m ² once daily for first two weeks followed by 240–400 mg/m ² in two divided doses	Severe hepatotoxicity, severe skin rash, hypersensitivity reaction Nausea, headache, fever	EFV. If NNRTIs not tolerated-boosted PIs —
Lopinavir/Ritonavir (LPV/r) (PI)	Hepatic	Oral	450 mg LPV with 115 mg ritonavir/m ² in two divided doses	Hepatotoxicity, pancreatitis, lipoatrophy or metabolic syndrome, dyslipidemia, severe diarrhea	< 3 years- NVP > 3 years- EFV
Nelfinavir (NFV) (PI)	Hepatic	Oral	110–130 mg/kg in two divided doses	Gastrointestinal symptoms, hepatitis, lipid abnormalities	—
Ritonavir (RTV) (PI)	Hepatic	Oral	Begin with 400 mg/m ² and titrate up to 800 mg/m ² in two divided doses	Gastrointestinal symptoms, pancreatitis, hepatitis, lipid abnormalities	—
Enfuvirtide (Fusion inhibitor)	Hepatic	Subcutaneous injection	>6 years age: 4 mg/kg in two divided doses	Local site reactions, immune-mediated reactions, hypersensitivity	—

Abbreviations: NRTI, nucleoside reverse transcriptase inhibitors; NNRTI, non-nucleoside reverse transcriptase inhibitors; PI, protease inhibitor.

vaccine, pneumococcal, varicella and hepatitis A vaccine are also recommended. However, immunizations may not always offer adequate protection in HIV-infected children.

Nutrition

Early nutritional intervention is important due to interrelation between nutrition, growth and HIV infection. Nutritional assessment and growth monitoring should be done in infants (monthly)

and children (3 monthly). Energy intake of asymptomatic HIV-infected children should be increased by 10% of recommended dietary allowance (RDA) and that of symptomatic children by 20–30% of RDA due to increased energy expenditure. In severe malnutrition, energy intake should be increased by 50–100% of RDA. Counseling should include micro- or macronutrient deficiency, selection of locally available good foods, vitamin A supplementation and information regarding food and water hygiene.

Table 9 The indications for starting antiretroviral therapy (ART) and first-line regimen in children

Population	Indication to start ART	Recommended ART
Infants < 12 months of age	Initiate in all HIV infected irrespective of CD4 count or WHO clinical staging. (all children < 5 years of age) Start as priority in HIV infected 1–2 years old or with severe/advanced HIV disease (WHO clinical stage 3 or 4) or CD4 cell count ≤ 750 cells/mm ³ or < 25% whichever lower. Any child < 18 months if presumptive clinical diagnosis of HIV.	Regardless of NNRTI exposure: LPV/r based regimen + 2 NRTI [ABC+ 3TC OR AZT+ 3TC] If LPV/r not feasible: NVP based regimen Where viral load monitoring is available, consideration can be given to substituting LPV/r with an NNRTI after virological suppression is sustained. If child on TB therapy; ABC + 3TC + AZT and replace with initial therapy once TB treatment over.
Between 12 and 24 months		Same as above
Between 24 months and < 5 years of age		24 months to < 3 years: Same as above
Children > 5 years of age	CD4 count ≤ 500 cells/mm ³ (irrespective of WHO staging) OR WHO clinical stages 3 and 4 (As priority in all children with severe/advanced HIV disease (WHO clinical stage 3 or 4) or CD4 cell count < 350 cells/mm ³) OR Active TB disease	> 3 years: EFV (or NVP alternative) + 2NRTIs 3–10 years old (< 35 kg): EFV (or NVP) + ABC+3TC EFV (or NVP) + AZT or TDF + 3TC (or FTC)
Adolescents (10–19 years old)	Same as above To start ART regardless of CD4 count or WHO staging if: Active TB disease, HBV coinfection with severe chronic liver disease	10–19 years old (>35 kg): EFV (or NVP) + TDF + 3TC (or FTC) EFV (or NVP) + AZT + 3TC EFV (or NVP) + ABC + 3TC
Children with TB	Start as above	< 3 years of age: NVP + 2 NRTIs OR 3 NRTIs [AZT or d4T+(3TC+ABC)] triple nucleoside regime ≥ 3 years: EFV + 2 NRTIs (switch back to standard first line regimen of 2NRTI + NVP after 2 weeks of completing rifampicin based ART) OR 3 NRTIs NVP + 2 NRTIs (avoid AZT)
Children with anemia	ART should be initiated regardless of WHO clinical stage or CD4 cell count in adolescents with HIV and active TB	
Adolescents > 12 years with hepatitis B	ART should be initiated regardless of WHO clinical stage or CD4 cell count in adolescents coinfectd with HBV with evidence of severe chronic liver disease	Tenofovir disoproxil fumarate (TDF) + emtricitabine (FTC) or 3TC + NNRTI

Abbreviations: AZT/ZDV, zidovudine; NFV, nelfinavir; RTV, ritonavir; ABC, abacavir; ddI, didanosine; FTC, emtricitabine; 3TC, lamivudine; NRTI, nucleotide reverse-transcriptase inhibitors; d4T, stavudine; TDF, tenofovir; NNRTI, non-nucleoside reverse-transcriptase inhibitors; EFV, efavirenz; ETV, etravirine; NVP, nevirapine; PIs, proteases inhibitors; ATV/r, atazanavir + ritonavir; DRV, darunavir; LPV/r, lopinavir/ritonavir; RAL, raltegravir.

Supportive Treatment

Counseling about the importance of good hand washing, avoiding raw or undercooked food (prevent *Salmonella* infection), avoiding drinking or swimming in lake or river water or being in contact with young farm animals (to prevent *Cryptosporidium* infection), and the risk of playing with pets (to prevent toxoplasma from cats) is essential. Simple interventions like good general hygiene, dental care, adequate nutrition (including nasogastric and parenteral nutrition if required), balanced diet, timely immunizations, vitamin A supplementation, plotting weight and height on growth charts, provision of safe and stimulating environment, developmental evaluation and interventions like occupation therapy or speech therapy can help a child with HIV to be free of infections and grow well.

HIV in Adolescents

Special considerations should be given to developmental or growth delay often associated with delayed puberty. Modifications in ART

should be specific to adolescents. In case of Tanner stages I, II or III Pediatric ARV schedule is recommended while in Tanner stages IV or V—adult schedule is recommended. One must observe caution in adolescent girls while use of EFV (those at risk of pregnancy) and NVP (CD4 counts between 250 cells/mm³ and 300 cells/mm³ due to risk of rash or hepatic toxicity). Besides this, the issues pertaining to disclosure of HIV status and long-term adherence to ART should also be addressed.

PREVENTION

Use of antiretroviral (ARV) drugs in pregnancy and breastfeeding is recommended for the mother's health and to prevent infection in the exposed baby. It may also help reduce sexual transmission. In order to accelerate the global scaling up of ART and prevention of mother to child transmission (PMTCT) in resource poor settings, ensuring global access to ART by all pregnant women and attaining global goals of eliminating new pediatric infections (and keeping mothers alive), the recommendations by WHO have been

Table 10 World Health Organization (WHO) guidelines for prevention of perinatal transmission of human immunodeficiency virus (HIV)

<i>Prevention of perinatal transmission (WHO 2013 recommendations)</i>		
Based on National PMTCT options	Treatment in mother Triple ARVs fixed-dose combination of TDF + 3TC (or FTC) + EFV (including 1st trimester of pregnancy and women of child-bearing age)	Treatment in child <i>Begin at birth or when HIV exposure recognized postpartum</i>
<i>Option B:</i> Use of lifelong ART in all HIV infected pregnant and breastfeeding women	To start ART and continue even after delivery and cessation of breastfeeding	<i>If breastfeeding:</i> 6 weeks of infant prophylaxis with once daily NVP.
<i>Option B+:</i> Use of lifelong ART in only HIV infected pregnant and breastfeeding women. <i>Eligible</i> (CD4 count below 500 cells/mm ³ or clinical stage 3 or 4 disease at the time of ART initiation or in accordance with national guidelines. Assess for second line if clinical or laboratory indication of treatment failure during above period.	<i>Eligible for treatment:</i> Start ART and continue after delivery and cessation of breastfeeding <i>Not eligible for treatment:</i> Start ART and stop after delivery (if replacement feeding) and cessation of breastfeeding (1 week after breastfeeding ends). If replacement feeding stop ART after delivery.	<i>If replacement feeding:</i> They should be given four to six weeks of infant prophylaxis with once daily NVP (or twice-daily AZT).

Abbreviations: ARV, antiretrovirals; TDF, tenofovir; 3TC, lamivudine; FTC, emtricitabine; EFV, efavirenz; ART, antiretroviral therapy; NVP, Nevirapine; AZT, zidovudine; PMTCT, preventing mother-to-child transmission.

simplified and standardized into guidelines (2013) suggesting options B or B+ based on national policies and recommendations (Table 10).

HIV and Breastfeeding (WHO Recommendations)

WHO aims to increase the HIV-free survival of infants exposed to HIV through its recommendations on HIV and infant feeding. This necessitates a balance between the risk of HIV transmission through breastfeeding as compared to risk of malnutrition and increased infections due to unsafe feeding practices. Based on national or sub-national recommendations, WHO 2010 guidelines suggest to counsel and support mothers to either breastfeed with antiretroviral (ARV) intervention or avoid breastfeeding completely to prevent HIV transmission postpartum. In countries recommending breastfeeding with ARV drugs, HIV infected mothers should exclusively breastfeed for first 6 months, then continue breastfeeding for first 12 months of life and stop only when a nutritionally adequate and safe diet without breastmilk can be ensured. Mortality due to pneumonia, diarrhea and malnutrition can be minimized by breastfeeding for first 12 months, while presence of ARV drugs reduces risk of HIV transmission to the infants. It is necessary to consider the socioeconomic and cultural context of the population, availability and quality of health services, local epidemiology and main causes of infant and child mortality before making the choice of type of feeding. HIV-infected mothers should be provided with lifelong ART or ARV prophylaxis to reduce the transmission to the child. When ARV drugs are unavailable, breastfeeding may provide infants a greater chance of survival and mothers should be counseled to exclusively breastfeed for first 6 months of life and continue breastfeeding thereafter (unless environmental and social circumstances are safe and supportive of replacement feeding). The mothers who decide to stop breastfeeding should do so gradually over a period of 1 month. The mothers or infants receiving ARV prophylaxis should continue the ARV drugs for 1 week after fully stopping the breastfeed. In such cases, infants must be provided with safe and appropriate replacement feeds. For replacement feeding, it is necessary to ensure adequate sanitary facilities, safe water supply, sufficient replacement supply (to ensure normal growth and development), adequate hygiene, family support and access to comprehensive healthcare.

Other measures to reduce transmission of HIV from mother to child are as follows:

Pregnant Women with HIV

Early identification of mothers with HIV should be done to provide ART drugs to both mother and newborn baby. One must ensure recommended antenatal visits and pregnancy care, additional screening for sexually transmitted infections, nutritional support and counseling regarding infant feeding and family planning.

Labor and Delivery

If HIV status unknown in women in labor, rapid HIV testing should be done during labor or immediate postpartum to provide ART to both mother and baby as soon as possible if tested positive. There should be facility based delivery by trained skilled birth attendants and unnecessary instrumentation or premature rupture of membranes should be avoided. Universal precautions should be carried by health workers as a usual norm. The baby's mouth and nostrils should be wiped as soon as head is delivered, infant should be handled with gloves till all maternal secretions and blood are wiped off and cord should be clamped (without milking) soon after birth.

Postdelivery

Provision of follow-up, linkages to treatment and postpartum care should be ensured. Child should be provided with initial care during first immunization visit (4–6 weeks of age), including reinforcing safe feeding measures, early infant diagnosis and ARV coverage while mother should be provided with postpartum check-up, family planning advice and review of ARV coverage and adherence support.

The Indian Government set-up the National AIDS Control Program (NACP I) and the National AIDS Control Organization (NACO) in 1992. The State AIDS Control Societies (SACS) were set up in 25 societies and 7 union territories. As the focus gradually shifted to decentralization, bringing behavioral changes and involving the non-governmental organizations (NGOs) and people living with HIV, subsequent phases were launched—NACP II in 1999 and NACP III in 2007. The Government is designing the strategy for NACP IV for period of 2012–2017, its main objectives being reduction of new infections, providing comprehensive care

and support to all people living with HIV and treatment facilities for all those requiring it. The main strategies are intensification and consolidation of preventive services, increased access and promotion of comprehensive care, support and treatment, expanding information education communication (IEC) services, building capacities at national, state, district and facility levels and strengthening strategic information management systems.

IN A NUTSHELL

1. Initially a disease of the so called *high-risk population*, HIV/AIDS has gradually and eventually penetrated upto all sections of the society.
2. With better access to antiretroviral therapy (ART), better drugs to treat opportunistic infections (OIs), the (HIV) disease has now been converted to a chronic disorder with longer survival and newer complications.
3. HIV is a multiorgan disease with varied manifestations in children due to their immature and developing immunity, allowing dissemination amongst all organ systems.
4. Clinical presentation are different in developing world where conditions like measles, tuberculosis, varicella, acute/persistent/recurrent diarrhea, etc. exist and contribute to the morbidity and mortality.
5. Failure to thrive (50–70%), hepatosplenomegaly (40–70%), anemia (40–50%), fever (30–60%), lymphadenopathy (40%), coinfection with TB (30–50%), diarrhea (20–30%), candidiasis (20%) and CNS symptoms (5–15%) are common presenting symptoms in children.
6. Children with HIV are increasingly susceptible to opportunistic infections (OIs), most common amongst which are *Pneumocystis carinii* (*jiroveci*) *pneumonia* (PCP), tuberculosis, recurrent bacterial infections, candidiasis, etc.
7. The diagnosis is by virological or serological methods. Presumptive diagnosis can also be made by certain clinical criteria in children less than 18 months where virological methods are unavailable.
8. Success of ART depends on appropriate drug selection, adherence, monitoring on ART, regular follow-up, knowledge of toxicities and drug interactions, diagnosing treatment failure early and appropriate change of ART.
9. Use of antiretroviral (ARV) drugs in pregnancy and breastfeeding is recommended for the mother's health and to prevent infection in the exposed baby.
10. Improved survival of infants exposed to HIV is aimed for through national or sub-national recommendations on HIV and infant feeding.

PROGNOSIS

The prognosis in HIV-infected children depends on availability and access to good health-care and medications (including ART). In the developed countries, progression of the HIV disease and the consequent mortality has decreased with an improved quality of life. A high viral load (>100,000 copies/mL) or CD4 lymphocyte percentage of below 15% is associated with higher mortality and morbidity. In developing countries, clinical staging system can

be effectively used to predict progression of the disease. Patients with lymphadenopathy, hepatosplenomegaly, parotitis and LIP have a comparatively better outcome. Those with OIs (PCP or MAC), severe wasting syndrome or encephalopathy have a poorer prognosis. Also, manifestations like persistent fever, serious bacterial infections (meningitis, pneumonia or sepsis), hepatitis and persistent anemia (<8.0 g/dL) with or without thrombocytopenia (<100,000/mm³) predict a poorer prognosis.

Section 32 PARASITIC INFECTIONS AND INFESTATIONS

Section Editors Ritabrata Kundu, Piyush Gupta

Chapter 32.1

Epidemiology of Parasitic Infections

Piyush Gupta, VG Ramachandran

BURDEN OF PARASITIC INFECTIONS

Parasitic infestations are widely prevalent in many developing countries, especially in the tropical and subtropical regions. These infections exert a significant effect on quality of life; and economic deprivation accrued through loss of human work hours. In an urban setting, parasitic infections in children result from ingestion of contaminated food and water or close association with their pets.

Epidemiology of parasitic infections is quite complex because of the involvement of various animals in their transmission cycle and a host of inter-related factors like environmental changes, human settlement, human behavior, food habits, population variation in animals, vectors and their densities, climate, etc., which influence the prevalence of the disease. Therefore, designing preventive and control measures is also not so simple.

Factors Influencing Prevalence

Behavioral Patterns

Human behavioral patterns including the habits, customs, traditions and socioeconomic practices are closely related to the risk of acquiring parasitic infections. Trekking, tourism, hunting, riding, mountaineering, fishing, other recreational activities and travel have increased this risk; also religious and sociocultural practices influence the prevalence of taeniasis in the community.

Food Habits

Food, food products and food habits have a role in the transmission of parasitic infections. Food-borne parasitic infections may be:

- *Directly transmissible* to humans by consuming food in which the infective stages of the parasite are naturally present, as in *Taenia*, *Trichinella*, fish-borne trematodes, *Diphyllobothrium*, *Gnathostoma*, *Angiostrongylus*, *Capillaria*, *Toxoplasma*, and *Linguatula*, or
- *Indirectly transmissible* to humans by food contaminated with infective stages of parasites derived from the environment, as with *Dracunculus*, *Echinococcus*, *Trichostrongylus*, *Trichuris*, *Fasciola*, *Ascaris*, *Toxocara*, *Toxoplasma*, *Giardia*, and *Entamoeba*, etc.

Consumption of uncooked or inadequately cooked fish and crustaceans may result in the transmission of *Diphyllobothrium latum*, *Clonorchis sinensis*, *Paragonimus westermani* and *Metagonimus*. Hydatid disease, taeniasis, toxoplasmosis and trichinosis are common parasitic infections transmitted to man through consumption of inadequately cooked meat or contamination of meat after cooking. Modern abattoir facility, stringent inspection at all stages of production, processing,

marketing, and health education are important in the control of meat-borne parasitic zoonoses.

Occupation, Migration and Settlement

Agricultural workers are more prone to vector-borne diseases and helminthiasis. Fishermen, cooks, abattoir workers are at higher risk of food-borne parasitic infections. Migration of human populations contributes significantly to the introduction of parasitic infections to new areas. Malaria, dracunculiasis, filariasis and hookworm infestations were introduced into the western world from Africa. Travel and migration may be responsible for spread of diseases to nonendemic areas; an example is *airport malaria* whereby infected mosquitoes can reach nonendemic areas. Household pets such as dogs, cats and other domestic animals may transmit toxoplasmosis and echinococcosis to their owners. National parks and wildlife sanctuaries also provide optimum conditions for perpetuation and transmission of different parasites.

Environmental Pollution

Climate, food supplies and hydrodynamic changes influence the perpetuation and dissemination of parasitic zoonosis. Fecal contamination of soil, water supply and vegetables is an important mode of environmental pollution that significantly influences the prevalence of parasitic disease, especially geohelminths, in both rural and urban areas. Stagnation of water and inadequate drainage increase breeding sites of the insect vectors of many parasitic infections.

Human activities such as irrigation schemes, construction of dams and other water reservoir development projects, establishment of new settlements, agricultural and industrial activities, affect the ecosystem in a way that makes it conducive for spread of parasitic infections.

HOST-PARASITE RELATIONSHIP

Parasites live in, on, or at the expense of the living organism. *Obligatory parasites* cannot complete their life-cycle without passing through a host. A few parasites, e.g., *Strongyloides stercoralis* are capable of living and completing their development even without a host. These are called *facultative parasites*.

Definitive Host

Man is the definitive host for many helminths. The adult and the sexual forms of parasites live in the body of the man, e.g., *Ascaris lumbricoides*, *Enterobius vermicularis*, *Ancylostoma duodenale* and *Necator americanus*. The parasites, however, may be capable of completing their life-cycle in other animals beside man. These animals serve as reservoirs of infection.

Intermediate Host

The intermediate host harbors the larval, immature or asexual forms of the parasite. Man is the intermediate host as well as the definitive host for some helminths, e.g., *Taenia solium* and *T. saginata*. Cattle are the intermediate hosts for *T. saginata* and pigs for *T. solium*, man for *Echinococcus* and fish for *Diphyllobothrium latum*.

At times, further development of the larval forms in the intermediate host is arrested; no further multiplication occurs and the parasite gets encysted, e.g., in cysticercosis caused by *T. solium*.

Infective Forms

- Eggs *Ascaris lumbricoides* and *Enterobius vermicularis*. In case of *Taenia solium*, and *T. saginata* the eggs develop into larvae in the intestines. The larvae pierce the gut wall and are encysted in various tissues.
- Larvae *Ancylostoma duodenale*, *Necator americanus* and *Strongyloides stercoralis*; cyclops, *Dracunculus medinensis*, cercaria, fasciolopsiasis, schistosomiasis.
- Cysts of larvae in cases of *Taenia solium* and *T. saginata* remain embedded in the flesh of pigs or cattle and may be eaten by man, developing into adult worms in the intestine.

SOURCES

Parasitic infections may be acquired from human, animal or inanimate sources.

Human Source

Infected individuals having amebiasis, pinworms and dwarf tapeworm infections are responsible for direct transmission of the infection to other human hosts.

Animal Source

Herbivores are an important source of infection to man. *T. saginata* is acquired by eating beef. Dogs are responsible for the transmission of hydatid disease. Blood sucking arthropods transmit malaria, leishmaniasis, trypanosoma and filariasis. Certain animals like sheep, cattle, pigs, etc., may serve as reservoirs of parasitic infections.

Inanimate Sources

Water may get contaminated with cysts of intestinal flagellates, protozoans, and cercariae of blood flukes. Soil may harbor eggs of roundworm, hookworm, *Trichuris* and *Strongyloides*. *Enterobius* can be transmitted via infected bed clothes, etc.

TRANSMISSION

Ingestion and inoculation are the two primary routes of transmission of infection to man. Certain other and less frequent routes of transmission are congenital, venereal and through inhalation.

Ingestion

Ingestion of food or drinks contaminated with cyst or ova of intestinal parasites, free infective larvae of *Trichostrongylus* spp. and the mature larval stages of intestinal flukes, lung flukes, *Trichinella spiralis*, *Diphyllobothrium latum*, *Taenia saginata* and *Taenia solium* may transmit the infection. *Ascaris lumbricoides*, *Enterobius*, *Hymenolepis nana*, *T. solium* infections may occur by eating food contaminated with the eggs. *Dracunculus medinensis* infection occurs by taking water containing the cyclops, the intermediate host.

Inoculation

Plasmodium, *Leishmania*, *Trypanosoma*, *Babesia*, and filarial parasite are transmitted by the bite of arthropod vectors. The infective forms of hookworms, schistosome and *Strongyloides stercoralis* pierce intact skin to invade the human body.

Other Routes

Toxoplasma gondii can cross the placenta causing congenital infection of the fetus; less frequently, malaria may be transmitted transplacentally. *Trichomonas vaginalis*, *Entamoeba histolytica*

and *Giardia lamblia* may be transmitted by vaginal and anal sexual contact respectively. Eggs of pinworm can occasionally be air-borne and transmitted by inhalation. *Strongyloides* and *Ancylostoma* may be transmitted occasionally by the transmammary route. *Plasmodium*, *Trypanosoma* and some other parasites may be transmitted by blood transfusion.

PATHOGENESIS

Parasitic infections invoke a variety of host reactions which depend on several factors: number of invading parasites, the growth, development and multiplication of parasite inside the host, and the sites of attachment of parasites. The reactions of the host to infection by the parasite may range from subclinical latent infection to the development of an overt clinical illness which may be mild, severe or fulminant. The various methods by which parasites may cause damage to the host are as follows:

Invasion

Hookworm, *Strongyloides*, *Enterobius* or *Taenia* attach to the intestinal wall causing traumatic damage to the intestinal villi. Hookworm attachment and their migration to another site may cause bleeding from the initial site. The usual losses are 0.04–0.15 mL of blood per worm per day resulting in anemia. Roundworms may also deprive the host of the nutrients.

Mechanical Damage

Roundworms or tapeworms may cause intestinal obstruction. They may also cause jaundice by blocking the ampulla of Vater; hydatid cysts may form large masses in the liver, lungs or other viscera; cysticerci may lodge in vital parts of the body including brain. In schistosomiasis, deposition of eggs inside the urinary bladder or intestinal mucosa leads to hemorrhages in the lumen of these organs.

Direct Trauma

Several helminthic larvae cause traumatic damage in lungs during their migration. *Paragonimus* infects lungs leading to its direct trauma. Identical damage may occur in the cerebral, renal or retinal capillaries and can be serious and often fatal.

Allergic Manifestations

Certain parasites may release their metabolic by-products into circulation which may behave like foreign antigens and produce a variety of allergic manifestations in the sensitized host. In dracunculiasis, migration of the gravid female to surface of the skin produces a local blister and an allergic reaction due to the release of the excretory or metabolic by-products of the parasite. Dracunculiasis and trichinellosis may also result in anaphylactic reactions, urticaria and eosinophilia. Hydatid cyst in the body cavity may rupture resulting in anaphylactic manifestations; fluid from *Ascaris* can also produce anaphylactic reactions. Cerebral cysticerci may die following chemotherapy leading to intense allergic reactions, brain edema and death. *Toxocara canis* may cause severe tissue damage due to hypersensitivity reaction.

Lysis and Necrosis

Entamoeba histolytica secretes several lytic enzymes. These include proteases, collagenases and perforins, etc., which digest intestinal tissue and also aid in the penetration and perforation of the large intestine. The parasites obtain their nourishment from lysed cells and utilize this energy for their growth and multiplication.

Inflammation

An acute inflammatory reaction occurs in various muscular tissues, around the larvae of *Trichinella*. Trichinellosis and strongyloidiasis

are invariably associated with eosinophilia. *E. histolytica* produces an intense tissue reaction in the large intestine of the host resulting in the formation of amebic granuloma. The eggs of the blood flukes deposited inside the vesical and intestinal mucosa incite local inflammatory reactions ending up in the evolution of granulomas that may undergo carcinomatous changes in prolonged and chronic infections.

Blood Loss

Destruction of red blood cells in malaria, mechanical loss of blood in hookworm infection or extensive invasion of the colon in intestinal amebiasis, frequently stimulates increased erythropoiesis in the body.

Chapter 32.2

Malaria

Ritabrata Kundu

Malaria is a major health problem in India. Though the total number of malaria cases has decreased from near 2 million per year in the beginning of this millennium to 1.5 million in last few years but the percentage of falciparum malaria contributing to the burden is on rise. At present falciparum malaria constitute 50% of total malaria cases in India. Malaria now is a dual species infection with equal contribution by both *Plasmodium vivax* and *Plasmodium falciparum*.

ETIOLOGY

Four species of the genus *Plasmodium* namely *P. vivax*, *P. falciparum*, *P. ovale* and *P. malariae* are mainly responsible for malaria. Of these, first two accounts for nearly all the cases of malaria in India. Few cases of *P. ovale* are reported from Orissa. The disease is not seen 2,000 m above mean sea level and thrives in high humidity with ambient temperature between 20°C and 30°C. The disease is transmitted by female anopheline mosquito with *Anopheles stephensi* and *Anopheles culicifacies* as the main vectors in urban and rural areas, respectively.

EPIDEMIOLOGY

The disease initially restricted to rural areas of eastern and northeastern states of India has also spread to the central and arid western parts of the country. Thereafter due to unplanned expansion of the megacities and town, urban malaria starting as a minor problem, has expanded to contribute about 10% of total malaria cases. The magnitude of the problem was further enhanced by *P. falciparum* developing resistance to first-line drug chloroquine (CQ). Despite a few stray reports of CQ resistant *P. vivax*, the drug at present still retains its efficacy against vivax malaria.

CQ resistant falciparum, first detected in northeastern part of India, has spread across. At present about 80 districts of 21 states of India report CQ resistant falciparum malaria. Resistance to second-line antimalarial drugs sulfadoxine-pyrimethamine (SP) has been reported from seven northeastern states, Orissa and few districts of West Bengal. Factors responsible for resistance include unplanned development, deforestation, population movement, infrastructure deficiency, and haphazard use of antimalarial drugs, and presumptive treatment based on clinical signs alone.

TRANSMISSION

Malaria in India has unstable transmission dynamics. The disease is seasonal increasing during and following monsoon rains. Hence, the population has little or no immunity toward malaria and all age groups are at risk of developing the disease. In some foci where the transmission is intense round the year particularly forested areas it is the child who bears the brunt of the disease. Children have lost the little immunity they acquired from their mother after infancy and have not yet developed immunity of their own.

PATHOGENESIS

Malaria is transmitted to human by the bite of female anopheline mosquito. Sporozoites from the mosquito enter the circulation and are taken up by the hepatocytes to produce merozoites. With rupture of the liver cells merozoites are liberated in the blood

stream. In case of vivax malaria some sporozoites in liver cells instead of multiplying to merozoites assume an inert stage known as hypnozoites. These hypnozoites may become active after weeks or months to cause relapse in vivax malaria. Hypnozoites are not produced in falciparum malaria hence there is no relapse. Merozoites from ruptured liver cells in blood enter the red blood cells (RBCs) with vivax showing preference for young cells and falciparum without any preference. Hence, more red cells are invaded in falciparum malaria as compared to vivax. During this phase of erythrocytic cycle also known as erythrocytic schizogony, malaria parasite passes through the stages of early ring form, trophozoite, schizont and merozoite. Ultimately the parasite occupies the entire red cell which becomes rigid and deformed with full of merozoites. Swollen red cell ruptures with release of multiple merozoites which again invades fresh red cells to start a new asexual cycle.

In *P. vivax* malaria the cycle of erythrocyte schizogony is completed in the peripheral circulation. Schizogony in falciparum malaria occurs in the capillaries of the internal organs like spleen, liver, brain, etc., with only the early ring forms usually seen in the peripheral blood. RBC containing the mature forms of falciparum parasite, i.e., beyond early ring form renders the red cells sticky. This causes two important problems in falciparum malaria parasitized RBC adhere to microvascular endothelium (*cytoadherence*) and also they adhere to uninfected erythrocyte (*rosetting*). The net result is impedance in forward flow of blood in venules and capillaries of vital organs leading to microcirculatory obstruction. When this obstruction involves the capillaries of brain it results in cerebral malaria and similarly in gut leads to algid malaria.

After a series of asexual cycles, some merozoites instead of developing into trophozoites and schizonts gives rise to male and female gametocytes, which are capable of sexual functions outside the human host. Gametocytes do not cause any fever in human host but are produced for propagation of the species. Female anopheles mosquito during its blood meal from an infected person ingests both male and female gametocytes. These gametocytes undergo series of developmental process in the mosquito with ultimate release of sporozoites, which concentrate in the salivary glands of the mosquito. Following the bite of an infected anopheline mosquito the sporozoites are introduced in the human to continue the cycle.

Besides obstructing the microcirculation of vital organs thereby interfering with tissue metabolism malaria causes destruction of RBC with liberation of parasites and degraded erythrocytes along with host reaction. Following malaria there is humoral response to infection which is not enough to contain the infection. Cell-mediated immunity against malaria is also ineffective as blood stage parasites in RBC do not express human leukocyte antigen (HLA) antigens.

Recrudescence of Malaria

Often due to incomplete treatment some erythrocytic form of parasite survives in human host and only with time it multiplies and produces recurrence of symptoms of malaria. This is especially seen in case of *P. falciparum* malaria and is known as recrudescence. It can be seen as long as 10 weeks following treatment.

CLINICAL DISEASE

Malaria in India, unlike high transmission areas of Africa, fluctuates greatly over seasons and years. This seasonal variation hinders the population from acquiring lasting immunity against malaria. Hence all age groups suffer from acute malaria with chances of progression to severe malaria particularly in cases of *P. falciparum* infection.

It is very important to distinguish uncomplicated and complicated or severe malaria as the later needs highest level of patient care for favorable outcome. If treatment is delayed or ineffective in early uncomplicated stage of *P. falciparum* malaria, the parasitic mass will rapidly increase to produce organ dysfunction resulting in severe malaria.

Initial symptoms of malaria are nonspecific and may resemble any viral fevers like influenza. Both the species cause muscle ache, headache, lethargy and vague abdominal pain. *P. vivax* malaria may cause well defined fever paroxysm with chills and rigor. *P. falciparum* malaria on the other hand may cause erratic fever and it may not regularize to any definitive paroxysm. The classical stages with cold, hot and sweating features may not be seen. Children may be extremely lethargic, anorectic and at times irritable. As the disease continues, spleen and liver enlarge with developing anemia. Mild abdominal discomfort is common in malaria with occasional constipation or diarrhea. Respiratory rate may increase due to dehydration, acidosis and anemia. These symptoms and signs are nonspecific resembling many common infections in children. Thus symptomatic diagnosis of malaria invariably leads to overdiagnosis.

Complicated or Severe Malaria

Complicated or severe malaria is defined as symptomatic malaria with signs of severity or evidence of vital organ dysfunction. Severe malaria due to *P. vivax* is rare. Occasional severe manifestation in vivax malaria may be due to splenic rupture either traumatic or spontaneous. Other manifestations include severe anemia, hypersplenism and at times cerebral malaria. Most of the complicated malaria are due to *P. falciparum* and early recognition is of utmost importance. Any of the following clinical or laboratory features in presence of asexual parasitemia are suggestive of complicated or severe malaria:

- **Cerebral malaria** Unrousable coma not attributable to any other cause in a patient with falciparum malaria.
- **Severe anemia** Anemia is a common finding in severe malaria particularly in children and pregnant women. Hemoglobin in often below 5 g/dL and hematocrit below 15%.
- **Hypoglycemia** It is defined as whole blood glucose concentration less than 40 mg/dL (2.2 mmol/L).
- **Respiratory distress (acidosis)** It is defined as arterial or capillary pH below 7.35 or plasma bicarbonate concentration below 15 mmol/L.
- **Circulatory collapse or shock (algid malaria)** Defined as systolic blood pressure less than 50 mm Hg in children (1–5 years) or less than 80 mm Hg in adults.
- **Pulmonary edema** It is one of the grave complications of severe malaria but fortunately less common in children.
- **Abnormal bleeding and disseminated intravascular coagulation (DIC).**
- **Renal failure** Defined as serum creatinine more than 3.0 mg/dL or urine volume less than 0.5 mL/kg/hour in children or 400 mL in 24 hours in adults despite normal hydration.
- **Hemoglobinuria** This is due to acute intravascular hemolysis accompanied by hemoglobinuria.
- **Jaundice** Defined as serum bilirubin more than 3 mg/dL or presence of clinical jaundice. If present with other signs of severe malaria then it is significant.
- **Hyperparasitemia** There is no agreed definition of hyperparasitemia. In high transmission area if the proportion of parasitized RBCs is 10% or more and in low transmission area the proportion is 5% more, then it is taken as hyperparasitemia.

Severe malaria in children is an emergency. Unlike adults, uncomplicated malaria progressing to severe malaria is rapid within 1 day or 2 days but resolution of coma is also rapid. Common

manifestations of severe malaria in children are cerebral malaria, severe anemia, respiratory distress with acidosis and hypoglycemia. Mortality is high in children in deep coma with acidotic breathing. Jaundice and pulmonary edema are uncommon in children and renal failure is a rare entity. Neurological sequel following cerebral malaria is more frequent in this age group as compared to adults.

DIAGNOSIS OF MALARIA

Diagnosis of malaria based on symptoms should be discouraged as it invariably leads to overdiagnosis. All cases of suspected malaria should have a parasitological diagnosis and with advent of rapid diagnostic test which does not need expertise, it is available even in the periphery. However, in complicated malaria or malaria with danger signs presumptive treatment may be started before confirmation after collecting blood for examination.

Microscopic Diagnosis

Light microscopy of well-stained thick and thin films by a skilled microscopist has remained the *gold standard* for malaria diagnosis. Thick films are nearly 10 times more sensitive for diagnosis of malaria as larger amount of blood are there in a given area as compared to thin films. Species identification is better with thin films as morphology of the parasite and RBCs are well preserved.

Timing of sample collection should be as soon as malaria is suspected. It can be collected any time irrespective of fever and not necessarily only at the height of fever. Collection should be before administration of antimalarial, which causes detection of parasites difficult due to its morphologic alteration.

Smears should be prepared soon after collection, which enables better adherence of films to the slide and cause minimal distortion of parasites and red cells. In blood collected with anticoagulants films should be prepared within 2 hours for best results. Smear should be examined with 100X oil immersion objective. A minimum of 100 fields should be examined before concluding the slide to be negative. Once negative, samples may be examined for at least 3 consecutive days where clinical suspicion of malaria persists.

Rapid Diagnostic Tests

These are immunochromatographic tests (ICT) to detect plasmodium specific antigens in blood sample. Test employs monoclonal antibodies directed against targeted parasite antigens. Targeted antigens in currently available rapid diagnostic tests (RDTs) are described below:

- **Histidine rich protein II (HRP-II)** is actively secreted by asexual stages and young gametocytes of *P. falciparum* but not by mature gametocytes.
- A metabolic enzyme **parasite lactate dehydrogenase (pLDH)** is produced by all four species of plasmodia, both asexual and sexual (gametocytes) stages provided they are viable. Monoclonal antibodies produced against this antigen are of three groups. One specific for *P. falciparum* and the second specific for *P. vivax*. The other is panspecific antibody which reacts with all the four species of plasmodia, i.e., *vivax*, *falciparum*, *ovale* and *malariae* but unable to differentiate them individually. Commercially available kits can detect *falciparum*, *vivax* and other malaria but cannot differentiate *ovale* and *malariae* malaria.
- Certain new antigens like plasmodium aldolase, an enzyme of the glycolytic pathway produced by all four species has been recently developed.

In India where falciparum and vivax malaria parasite cocirculate, typically occurring as a single species infection; a RDT which can detect both falciparum and vivax malaria and also distinguish between them is warranted. There are some

commercially available kits, which detect falciparum specific LDH and panspecific LDH. They can distinguish between falciparum from nonfalciparum malaria. Problem with these kits are two-fold: firstly they cannot distinguish falciparum malaria from mixed infection, secondly as vivax malaria is almost the only non-falciparum malaria in India so often they equate nonfalciparum malaria with vivax malaria.

The World Health Organization (WHO) has recommended for RDTs a minimum standard of 95% sensitivity with *P. falciparum* densities of 100 parasite/μL of blood and a specificity of 95%. RDTs using HRPII are generally more sensitive than RDTs detecting *P. falciparum* specific pLDH. *P. vivax* specific monoclonal antibodies have undergone limited evaluation. Unfortunately independent peer reviewed evaluation for most commercially available RDTs is not available. In general with high parasite density these tests are fairly sensitive but with low parasite load sensitivity decreases often yielding false negative results. False positive result may also develop when gametocytes are present but asexual stage parasites are eradicated by therapy.

HRPII antigen persists at detectable levels for more than 28 days even after successful therapy. Aldolase and pLDH rapidly fall to undetectable levels after initiation of effective therapy but these antigens are expressed in gametocytes which may appear after clinical infection is cleared. So none of the RDTs are useful for monitoring the response to treatment for which microcopy is the investigation of choice. However, they are usually simple without much training requirement, easy to interpret, and results are available rapidly. The stability of the kit in high environmental temperature and humidity of tropics should be taken into account.

Role of RDTs in the Diagnosis of Malaria in India

Microscopic diagnosis needs expertise and is unavailable in remote parts with poor health infrastructure. So RDTs will be useful in following situations in India:

- In remote areas with poor health infrastructure where microscopic diagnosis is not available. Also in areas where laboratory service is inadequate, of an unacceptable standard or not available at odd hours.
- In places where both RDT and microscopy are available they can complement each other. RDTs will provide screening diagnosis in suspected cases whereas microscopy reserved for resolution of doubtful cases, confirmation of negative result in RDTs with high clinical suspicion of malaria.
- Microscopy may fail to demonstrate parasite due to sequestration in capillaries of the organs whereas RDT can pickup antigen in this cases.
- According to the National drug policy of malaria (2013) all fever cases clinically suspected of malaria should be investigated for confirmation of malaria by microscopy or RDT.

RDTs permit on the spot confirmation of malaria even at the peripheral health-care system, by unskilled health worker with minimal training. This will reduce unnecessary treatment based on symptomatic diagnosis hence in turn decrease drug pressure.

Other Methods of Diagnosis

Other diagnostic methods namely microscopy using fluorochromes, molecular probes, polymerase chain reaction (PCR) and serology are available. Unfortunately they are not suitable for routine disease management and their use is currently for only research and epidemiological purpose.

MANAGEMENT OF UNCOMPLICATED MALARIA

Malaria parasite develops resistance to drugs randomly due to *de novo* genetic mutations. As nonimmune patients in India are

infected with large number of parasites, if they receive inadequate treatment are a potent source of *de novo* resistance. Here lies the importance of prescribing highly effective treatment regimen in high parasitemic patients and ensuring good adherence to prescribed drugs.

It has been noted that monotherapy for falciparum malaria invariably results in failure. Sulfadoxine-pyrimithamine introduced following CQ resistance fell rapidly to resistance in the early 1980s. Whereas mefloquine (MQ) introduced as monotherapy for falciparum malaria took only 4–5 years to report resistance. To counter the threat of resistance of falciparum to monotherapy, WHO now recommends combinations of antimalarials for the treatment of falciparum malaria.

Antimalarial Combination Therapy

Antimalarial combination therapy is the simultaneous use of two or more blood schizonticidal drugs with independent mode of action and targeting different biochemical stages in the parasite. If two drugs with different mode of action and different resistance mechanism are used in combination then the probability of developing resistance to both drugs is the product of their individual per parasite probabilities. If a mutant parasite develops *de novo* resistance during the course of infection to one drug it will be killed by the other drug. However, to reap the benefit of combination therapy the partners in the combination should be individually effective. This mutual protection will prevent or at least delay emergence of resistance to individual drug. The only disadvantage of combination therapy is increased risk of adverse effect and increased cost of therapy.

According to WHO, one of the partners in combination therapy will be artemisinin and its derivatives hence known as artemisinin-based combination therapy (ACT). The reason for choosing artemisinin is its rapid clearance of parasitemia and resolution of symptoms. They reduce the parasite number by approximately 10,000 fold (10^4) in each asexual cycle. The second important reason is its rapid elimination from the body so that the residual concentration of the drug does not provide a selective filter for resistant parasites. The other reasons are its lack of serious adverse effects, absence of significant resistance till date, and reducing gametocyte carriage due to its gametocytocidal action.

Artemisinin if combined with other rapidly eliminated antimalarials like tetracycline or clindamycin, a 7 days course of treatment is required. This long course invariably results in poor adherence. But when combined with slowly eliminated antimalarials like SP, MQ or lumefantrine, shorter courses of treatment (3 days) will be effective and also ensure adherence. In 3 days ACT regimen, artemisinin is present in the body during the two asexual parasite life cycles each lasting for 2 days. This treatment reduces the number of parasites in the body by a factor of approximately one hundred million ($10^4 \times 10^4 = 10^8$). The complete clearance of the parasites is dependent on the partner medicine being effective and persisting at parasitocidal concentration until all the infecting parasites have been killed. Thus the partner compound is to be relatively slowly eliminated.

As a result of combination therapy the artemisinin component is protected from resistance by the partner medicine provided it is efficacious and partner medicine is in turn protected by the artemisinin derivative.

The following ACTs are currently available in India:

- Artesunate (AS) + SP
- Artesunate + MQ
- Artemether + Lumefantrine

Of these, artemether-lumefantrine is available as coformulated tablets and liquid preparation. Lumefantrine is not available as

monotherapy, and it has been never used alone for the treatment of malaria. Other combinations are available separately.

Treatment Regimes for Uncomplicated Malaria

Treatment regimens are to be tailored specifically according to the resistance pattern of the region under consideration. However, in view of gradually increasing resistance it has been decided that all falciparum cases should be treated with ACT both in public or private health-care system to win the war against ongoing drug resistance. All cases of mixed infection, i.e., *P. vivax* and *P. falciparum* are to be treated as falciparum malaria along with primaquine for 14 days. Treatment regimes are to be tailored specifically according to the resistance pattern of the region under consideration (**Boxes 1 to 3**).

BOX 1 Recommended treatment of uncomplicated *P. vivax* malaria

Recommended treatment

Chloroquine 10 mg base/kg stat orally followed by 5 mg/kg at 6, 24 and 48 hours (total dose 25 mg/kg)

OR

Chloroquine 10 mg base/kg stat orally followed by 10 mg/kg at 24 hours and 5 mg/kg at 48 hours (total dose 25 mg base/kg)

Primaquine should be given in a dose of 0.25 mg/kg once daily for 14 days to prevent relapse

- Chloroquine should not be given in empty stomach and in high fever. Temperature should be brought down first. If vomiting occurs within 45 minutes of a dose of chloroquine that particular dose is to be repeated after taking care of vomiting by using antiemetic (domperidone/ondansetron).
- As primaquine can cause hemolytic anemia in children with G6PD deficiency they should be preferably screened for the same prior to starting treatment. As infants are relatively G6PD deficient it is not recommended in this age group and children with 14 days regimen should be under close supervision to detect any complication. In cases of borderline G6PD deficiency once weekly dose of primaquine 0.6–0.8 mg/kg is given for 6 weeks.

BOX 2 Recommended treatment of uncomplicated *P. falciparum* malaria in all states other than North-eastern states of India

Recommended treatment

Artesunate 4 mg/kg of body weight orally once daily for 3 days and a single administration of SP as 25 mg/kg of sulfadoxine (S) and 1.25 mg/kg of pyrimethamine (P) on day 1

OR

Artesunate as above and mefloquine 25 mg/kg of body weight in two divided doses (15 mg/kg and 10 mg/kg) on day 2 and day 3.

OR

Coformulated tablets containing 20 mg of artemether and 120 mg of lumefantrine can be used as a six dose regimen orally twice a day for 3 days. For 5–14 kg body weight 1 tablet at diagnosis, again after 8–12 hours and then twice daily on day 2 and day 3. For 15–24 kg body weight same schedule with 2 tablets. For 25–35 kg body weight and above same schedule with 3 and 4 tablets respectively.

AND

A single dose of primaquine (0.75 mg/kg) is given for gametocytocidal action.

- Currently there are insufficient safety and tolerability data on mefloquine at its recommended dosage of 25 mg/kg body weight in children. Mefloquine shares cross resistance with quinine which is still an effective drug in India. Health planners of India do not advocate use of mefloquine.
- Advantage of artemether-lumefantrine combination is that lumefantrine is not available as monotherapy and has never been used alone for the treatment of malaria. Lumefantrine absorption is enhanced by coadministration with fatty food like milk.
- Artemether-lumefantrine is not recommended in children weighing less than 5 kg.

BOX 3 Recommended treatment of uncomplicated *P. falciparum* malaria in North-eastern states of India

Recommended treatment

Coformulated tablets containing 20 mg of artemether and 120 mg of lumefantrine can be used as a six dose regimen orally twice a day for 3 days. For 5–14 kg body weight 1 tablet at diagnosis, again after 8–12 hours and then twice daily on day 2 and day 3. For 15–24 kg body weight same schedule with 2 tablets. For 25–35 kg body weight and above same schedule with 3 and 4 tablets respectively.

OR

Artesunate 4 mg/kg of body weight orally once daily for 3 days and mefloquine 25 mg/kg of body weight in two divided doses (15 mg/kg and 10 mg/kg) on day 2 and day 3.

AND

A single dose of primaquine (0.75 mg/kg) is given for gametocytocidal action.

Treatment Failure

Classification of treatment failure are based on both presence of fever or other signs of malaria along with peripheral parasitemia. Early treatment failure occurs if patients develops clinical or parasitological symptoms within first 3 days of follow-up. Late treatment failure is from day 4 to day 28 of follow-up. Treatment failure always doesn't mean resistance as poor adherence, poor drug quality and abnormal pharmacokinetic property of the patient may also be responsible. So, a proper treatment history is essential along with parasitological confirmation of failure by microscopy as RDTs (HRPII based) may remain positive for weeks following therapy. Failure within first 14 days of therapy should be treated with second-line antimalarials, which is quinine with tetracycline or doxycycline or clindamycin. Failure after 14 days of therapy which can be a new infection also may be treated with first-line ACT.

MANAGEMENT OF SEVERE MALARIA

Severe life-threatening malaria is nearly always due to *P. falciparum*. All cases with severe manifestations are to be treated in the same line of complicated malaria with injectable antimalarials irrespective of the species. High degree of suspicion of severe malaria is of utmost importance and any delay in initiation of treatment can be fatal. It should be treated as a medical emergency at highest level of medical facility available preferably in a intensive care setting. Confirmation of the diagnosis is preferable but one should not delay the treatment if it needs more than 1 hour. Further in cases of strong clinical suspicion prompt antimalarial therapy is needed even if parasite are not found in the initial blood examination. Effective therapy in children with severe malaria includes antimalarial chemotherapy, supportive management and management of complications. All these three interventions are equally important and to be taken care of simultaneously.

Antimalarial Chemotherapy of Severe and Complicated Malaria (Table 1)

Ideally, antimalarial drug should be given initially by intravenous (IV) infusion, which should be replaced by oral administration as soon as condition permits. Antimalarials should be given according to the body weight of the patient. If parenteral injection is not possible, referral is likely to be delayed and artemisinin is not available as suppository form crushed antimalarial may be given by nasogastric tube. It has the risk of causing vomiting and may produce inadequate drug levels in the blood. According to the National Antimalaria Program (NAMP), in all cases of severe malaria either IV quinine or parenteral artemisinin derivatives is to be given irrespective of CQ resistance status.

Table 1 Recommended treatment of complicated and severe malaria

Drug	Dosage
Quinine salt	<p>20 mg salt/kg (loading dose) diluted in 10 mL of isotonic fluid/kg by infusion over 4 hours. Then give a maintenance dose of 10 mg salt/kg every 8 hours, calculated from beginning of previous infusion, until the patient can swallow, then quinine tablets, 10 mg salt/kg 8 hourly to complete a 7 day course of treatment (including both parenteral and oral). Tetracycline or doxycycline or clindamycin is added to quinine as soon as the patient is able to swallow and should be continued for 7 days.</p> <p>Tetracycline (more than 8 years) or doxycycline (more than 8 years) to be given for 7 days 4 mg/kg/dose 4 times daily or 3.5 mg/kg once a day respectively. Clindamycin to be given 20 mg/kg/day in two divided doses for 7 days.</p> <p>If controlled IV infusion cannot be administered then quinine salt can be given in the same dosages by IM injection in the anterior thigh (not in buttock).</p> <p>The dose of quinine should be divided between two sites, half the dose in each anterior thigh. If possible IM quinine should be diluted in normal saline to a concentration of 60–100 mg salt/mL. (Quinine is usually available as 300 mg salt/mL). Tetracycline or doxycycline or clindamycin should be added as above.</p> <p style="text-align: center;">OR</p>
Artesunate	<p>2.4 mg/kg IV stat then at 12 and 24 hours, then once a day. Once the patients is able to swallow oral medication, complete the treatment by giving a course of</p> <ul style="list-style-type: none"> • Artemether plus lumefantrine in North-eastern states as shown in Box 3. • Artesunate plus sulfadoxine-pyrimethamine in all states other than North-eastern states of India as shown in Box 2. <p style="text-align: center;">OR</p>
Artemether	<p>3.2 mg/kg (loading dose) IM, followed by 1.6 mg/kg daily. Once the patients is able to swallow oral medication, complete the treatment by giving a course of</p> <ul style="list-style-type: none"> • Artemether plus lumefantrine in North-eastern states as shown in Box 3. • Artesunate plus sulfadoxine-pyrimethamine in all states other than North-eastern states of India as shown in Box 2.

- Parenteral treatment in severe malaria should be continued at least for 24 hours irrespective of patients ability to tolerate oral medication earlier than 24 hours.
- Loading dose of quinine should not be used if the patient has received quinine, quinidine or mefloquine within the preceding 12 hours. Alternatively loading dose can be administered as 7 mg salt/kg by IV infusion pump over 30 minutes, followed immediately by 10 mg salt/kg diluted in 10 mL isotonic fluid/kg by IV infusion over 4 hours.
- Quinine should not be given by bolus or push injection. Infusion rate should not exceed 5 mg salt/kg/hour.
- If there is no clinical improvement after 48 hours of parenteral therapy the maintenance dose of quinine should be reduced by one-third to one-half, i.e., 5–7 mg salt/kg.
- Quinine should not be given subcutaneously as this may cause skin necrosis.
- Artesunate, 60 mg per ampoule is dissolved in 0.6 mL of 5% sodium bicarbonate diluted to 3–5 mL with 5% dextrose and given immediately by IV bolus (push injection).
- Artemether is dispensed in 1 mL ampoule containing 80 mg of artemether in peanut oil.
- Mefloquine should be avoided in cerebral malaria due to neuropsychiatric complications associated with it.

Choice of Therapy

Artemisinins are the most rapidly acting of all known antimalarial drugs, they often produce a 10,000-fold reduction of parasites per asexual cycle. They have the broadest time window of antimalarial effects from ring forms to early schizonts. Thus they can stop parasite maturation, particularly from the less pathogenic circulating ring stages to the more pathogenic cytoadherent stages. Artemisinin also has an excellent safety profile and the cost of therapy as compared to quinine is almost similar. There are no reports of resistance to artemisinin at present but declining sensitivity to quinine has been reported from some Southeast Asian countries like Thailand. Randomized trials comparing artesunate and quinine from Southeast Asia show clear evidence of benefit with artesunate. However, artemisinin should be used when rate controlled IV infusion of quinine is not possible, patients have contraindications to quinine use and evidence of inadequate response or resistance to quinine noted. Simultaneous use of quinine and artemisinin is not indicated as it may be harmful and there is no added advantage. In limited studies available artesunate has been found to be better than artemether.

MANAGEMENT OF COMPLICATED AND SEVERE MALARIA

Of the various complications of falciparum malaria the common and important ones in children are as follows:

- Cerebral malaria
- Severe anemia
- Respiratory distress (acidosis)
- Hypoglycemia.

Cerebral Malaria

It may present like any other infection with fever followed by inability to eat or drink. The progression to coma or convulsion is very rapid within 1 or 2 days. Convulsions may be very subtle with nystagmus, salivation or twitching of an isolated part of the body. Other treatable causes of coma (e.g., bacterial meningitis, hypoglycemia) should be excluded. Good nursing care, management of convulsions with diazepam/midazolam and avoidance of harmful ancillary treatment like corticosteroids, mannitol, adrenaline and phenobarbitone is needed.

Severe Anemia

Children with hyperparasitemia due to acute destruction of red cells or malaria in children with already existing nutritional anemia may develop severe anemia. Packed red cell transfusion should be given slowly and cautiously when packed cell volume (PCV) is 12% or less, or hemoglobin is below 4 g%. Transfusion should also be considered in patients with less severe anemia in the presence of respiratory distress (acidosis), impaired consciousness or hyperparasitemia.

Lactic Acidosis

Deep breathing with indrawing of lower chest wall without any localizing chest signs suggest lactic acidosis. Commonly seen in patients with cerebral malaria, anemia or dehydration. Judicious fluid therapy to correct hypovolemia, treatment of anemia and

prevention of seizures are needed. Monitoring acid base status, blood glucose and urea and electrolyte level are also important.

Hypoglycemia

Common in children less than 3 years especially with hyperparasitemia or with convulsion and particularly in patients treated with quinine. As manifestations are similar to those of cerebral malaria so it can be easily overlooked unless looked for carefully hence monitor blood sugar every 4–6 hourly. If facilities to monitor blood glucose are not available assume hypoglycemia in symptomatic patient and treat accordingly. Correct hypoglycemia with IV dextrose and it should be followed by slow infusion of 5% dextrose containing fluid to prevent recurrence.

Hyperpyrexia

High fever is common in children and may lead to convulsion and altered consciousness. Tepid sponging, fanning and paracetamol 15 mg/kg should be given.

PREVENTION OF MALARIA

One of the main pillars of prevention is vector control which may be by chemical control, biological control and personal protective measure taken up by individuals or community. Indoor residual spraying has been there for a long time but mosquitoes develop resistance to it. Aerosol spray at day time and fogging with malathion are other methods of chemical control. Use of mosquito larvivorous fish in tanks and other water bodies where mosquitoes breed are ways of biological control. Screening of home with wire mesh gives personal protection. As mosquito bites from dusk to dawn, evening use of repellent cream, coils and mats are effective in preventing bite and also wearing long sleeve clothes are helpful. Sleeping under insecticide treated bed-nets is very effective. Environmental management by reduction of breeding places, proper storage of water and reducing of unplanned construction will go in a long way to prevent mosquito breeding. Finally it is the participation of the community in these activities is essential.

Malaria Vaccine

Despite considerable effort it seems a good vaccine against malaria is far from reality. A number of liver-stage antigen including circumsporozoites protein of *P. falciparum* were developed as

vaccine candidate but none proved to be effective. Of the blood stage vaccine, SPf66 developed in Columbia which contains a mixture of synthetic peptides of sporozoites and ring infected erythrocytes showed some promise initially but failed in trials conducted in Africa. Transmission blocking vaccines directed against gametocytes are also in the line. Finally multistage vaccines are also under study but none of the report shows any hope in near future.

IN A NUTSHELL

1. Parasitological diagnosis is important for malaria diagnosis as it prevents unnecessary drug usage.
2. Microscopy is still the gold standard of diagnosis, rapid diagnostic tests (RDTs) are reserved for areas without skilled microscopist.
3. Complicated malaria needs prompt recognition as success of therapy decreases with time.
4. For uncomplicated *P. vivax* malaria, chloroquine is the drug of choice.
5. All cases of falciparum malaria should be treated with artemisinin combination therapy (ACT) irrespective of drug resistance status.
6. All cases of complicated malaria should be treated with either IV artemisinin or quinine irrespective of species.
7. IV artemisinin is superior to quinine for treatment of complicated malaria.
8. Mosquito control is still most effective in malaria prevention as vaccine against malaria is not available.

Chapter 32.3

Leishmaniasis

Shyam Sundar, Jaya Chakravarty

Leishmaniasis, a vector-borne disease, is caused by an obligate intracellular protozoan of the genus *Leishmania*, order kinetoplastida, family Trypanosomatidae, and is transmitted by the bite of female sandfly vectors. Clinical manifestations range from self-healing cutaneous ulcers to systemic multiorgan disease. It broadly manifests as visceral leishmaniasis (VL, also known as kala-azar), cutaneous leishmaniasis (CL) and mucocutaneous leishmaniasis (MCL).

EPIDEMIOLOGY

Leishmaniasis is endemic in 98 countries with more than 350 million people are at risk. Approximately 0.2–0.4 million VL cases and 0.7–1.2 million CL cases occur each year. More than 90% of global VL cases occur in just six countries: India, Bangladesh, Sudan, South Sudan, Brazil and Ethiopia. In India, about 100,000 cases of VL are estimated to occur annually and the state of Bihar accounts for more than 90% of cases. There has been a significant decline in the annual incidence of VL in India in recent years. CL is more widely distributed, with about one-third of cases occurring in each of the three regions, the Americas, the Mediterranean Basin and western Asia from the Middle East to Central Asia.

TRANSMISSION

The only proven vector of human disease is sandfly of species *Phlebotomus* (Fig. 1) in the Old World (Asia, Africa and Europe) and *Lutzomyia* in the New World (the Americas). Transmission is of two types: anthroponotic, where the vector transmits the disease from human to humans; and zoonotic where the disease is transmitted from an animal reservoir to humans. Most CL have zoonotic transmission except those caused by *L. tropica*, which is predominantly anthroponotic. Human to human transmission of VL through infected needles have been reported among IV drug users in the Mediterranean region. *In utero* transmission to the fetus can occur rarely.

Figure 1 A blood fed female sandfly *Phlebotomus argentipes*

LIFE CYCLE

The life cycle of *Leishmania* has two distinct forms: promastigotes (length 10–20 μm), flagellar form found in the gut of the sandfly vector; and an aflagellar amastigote form (length 2–4 μm), which develops intracellularly in the vertebrate host. Promastigotes are introduced through the proboscis of female sandfly into the skin of the host. The neutrophils are among the first host cell that takes up the promastigotes. After the neutrophils undergo apoptosis the parasites are taken up by the macrophages and dendritic cells. Here they transform into amastigotes by losing their flagella and multiply. During feeding on infected hosts the sandflies inoculate the amastigotes which transform into promastigotes in their midgut. They multiply and then migrate to the anterior midgut and can infect a new host during blood feed.

VISCERAL LEISHMANIASIS (KALA-AZAR)

Visceral leishmaniasis is caused by the *Leishmania donovani* complex: *L. donovani*, the causative organism of VL in the Indian subcontinent and Africa, and children comprise about half of the victims; *L. infantum* (*L. chagasi*) which causes VL in the Mediterranean Basin, Asia, Central and South America primarily a disease of children in these regions. In South Asia and the Horn of Africa, the predominant mode of transmission of VL is anthroponotic. Patients with VL and those with post-kala-azar dermal leishmaniasis (PKDL) are the major reservoirs for the transmission. In the Mediterranean, the Middle East and Brazil, VL is zoonotic, with the domestic dog as the most important reservoir host sustaining transmission.

Immunopathogenesis

Infection does not always result in clinical illness and majority control the infection by mounting a successful immune response. The ratio of incident asymptomatic infections to incident clinical cases varies. In India asymptomatic infection is nine times more frequent than symptomatic VL. The host specific cell-mediated immune (CMI) response has an important role in controlling the infection. Studies in mouse model have shown that resistance to acquired leishmanial infection is controlled by the production of interleukin-12 (IL-12) by antigen presenting cells and subsequent secretion of interferon (IFN) γ , tumor necrosis factor (TNF) α and other proinflammatory cytokines by the T helper 1 (T_H 1) subset of lymphocytes. Patients with active VL have a mixed T_H 1 and T_H 2 response with high levels of IL-10 promoting the disease.

The organs of the reticuloendothelial system are affected primarily leading to enlargement of the spleen, liver and lymph nodes, though lymphadenopathy does not occur in the Indian subcontinent. Bone marrow dysfunction resulting in anemia and leukopenia occurs early and is followed by thrombocytopenia.

Clinical Features

In endemic areas of East Africa and India, the highest incidence is in children and young adults. In Southern Europe, North Africa and West and Central Asia, children in the age group of 1–4 years were most affected however with the increase in human immunodeficiency virus (HIV)-VL coinfection in Europe about half the cases are now in adults. The incubation period is believed to be 2–3 months but may be up to 1 year or more, and the onset of the disease is usually gradual. The common symptoms are fever with chills and rigor, malaise, weight loss, anorexia and discomfort in the left hypochondrium. The common clinical signs are non-tender splenomegaly which is usually palpable by 2 weeks and may become huge as the illness progresses, hepatomegaly is usually moderate, and there is wasting and pallor of mucous membranes (Fig. 2). Lymphadenopathy occurs commonly except in the Indian

Figure 2 A child with visceral leishmaniasis with hepatosplenomegaly

subcontinent. Blackish discoloration of the skin of the face, hands, feet and abdomen can occur (the vernacular name, *kala-azar*, means *black fever* or *deadly fever*). In Sudan, rarely a cutaneous nodule or ulcer or a mucosal lesion may be present, containing *Leishmania*. Signs of malnutrition (edema, skin and hair changes) develop as the disease progresses. Anemia can be severe and may lead to congestive heart failure. Thrombocytopenia can lead to epistaxis, retinal hemorrhages, and gastrointestinal bleeding. Intercurrent infections such as measles, pneumonia, tuberculosis, bacillary and amebic dysentery are common. Herpes zoster, chicken pox, boils in the skin and scabies may also occur. VL is usually fatal if left untreated.

Post-Kala-azar Dermal Leishmaniasis

In the Indian subcontinent 5–15% patients (highest in Bangladesh) with VL develop a chronic form of dermal leishmaniasis characterized by hypopigmented macules, papules and/or indurated nodules (**Figs 3A and B**), which is called post-kala-azar dermal leishmaniasis (PKDL). The dermal manifestations occur 6 months to 3 years after the cure of VL and spontaneous resolution is rare in the Indian subcontinent. On the other hand

Figure 3A Nodular form of post-kala-azar dermal leishmaniasis showing multiple nodules over face

in East Africa especially Sudan, up to 60% patients may develop PKDL, and is seen concurrently with VL or immediately thereafter within 6 months. In most patients, the skin manifestations resolve spontaneously, and only in a small minority treatment is needed.

HIV-VL Coinfection

It is a growing problem and has been reported from more than 35 countries. HIV infection increases the risk of developing VL by 100–2,320 times in areas of endemicity, reduces the likelihood of a therapeutic response, and greatly increases the probability of relapse. Initially, HIV-VL coinfection was reported from the Mediterranean countries, but the number of cases is increasing in sub-Saharan Africa especially in Ethiopia, Brazil and the Indian subcontinent. VL promotes the clinical progression of HIV. The clinical features are usually similar to a classic VL patient in majority of instances, however, in about one-fourth of cases there may be unusual manifestation with involvement of uncommon sites, e.g., infiltration of skin, oral mucosa, gastrointestinal tract, lungs and other organs.

Laboratory Diagnosis

Parasite Detection

The demonstration of the amastigote form of the parasite by microscopic examination of aspirates from bone marrow, spleen or lymph node is the gold standard for the diagnosis of VL (**Fig. 4**). Although the specificity is high, the sensitivity of microscopy varies, being higher for spleen (93–99%) than for bone marrow (53–86%) or lymph node (50%). Culture of these tissue aspirates further increases the sensitivity. However, splenic aspiration can be complicated by life-threatening hemorrhage, and requires considerable technical expertise.

Serological Tests

Serological tests based on indirect fluorescence antibody (IFA), enzyme-linked immunosorbent assay (ELISA) or western blot have shown high diagnostic accuracy in most studies but are poorly adapted to field settings. The direct agglutination test (DAT) and the rK39-based immunochromatographic test (ICT) are two serological tests that have been specifically developed for field use. Both DAT and rK39 ICT have very high sensitivity and specificity for VL however, rK39 in India, has lower sensitivity in East Africa. In the Indian subcontinent rK39 ICT has

Figure 3B A female child with macular form of post-kala-azar dermal leishmaniasis showing multiple depigmented macules over abdomen

Figure 4 A microphotograph of splenic smear showing multiple amastigotes inside a macrophage. Inside amastigotes, larger light stained nucleus and small dark stained kinetoplast can easily be identified

become very popular as it is easy to perform, rapid, cheap, yields reproducible results, and can be performed with a drop of finger prick blood, in difficult field conditions.

Antibody-based tests have some drawbacks, serum antibody levels remain detectable up to several years after cure, and therefore, VL relapse cannot be diagnosed by antibody detection. They are often negative in HIV positive patient. Owing to asymptomatic infections, up to 32% healthy individuals, living in endemic areas with no history of VL, are positive for antileishmanial antibodies. Thus antibody-based tests must always be used in combination with a standardized clinical case definition for the diagnosis of VL.

Molecular Diagnosis

The detection of parasite deoxyribonucleic acid (DNA) by polymerase chain reaction (PCR) in blood or bone marrow aspirates is very sensitive but is currently restricted to only referral hospitals and research centers.

Hematological and Biochemical Parameters

Anemia and leukopenia occur earlier than thrombocytopenia. Hepatic transaminases are elevated commonly and serum bilirubin may be elevated occasionally. Hypergammaglobulinemia resulting in reversal of albumin globulin ratio is common.

Differential Diagnosis

Febrile illnesses like malaria, typhoid, tuberculosis, brucellosis, schistosomiasis and histoplasmosis can mimic VL. In an endemic region, fever with splenomegaly, pancytopenia and hypergammaglobulinemia strongly suggests the diagnosis of VL. In nonendemic regions history of travel to endemic area needs to be elicited.

Treatment

Once the diagnosis is established, patients should be started on antileishmanial drugs. In addition, supportive therapy like good nutrition, blood transfusion and treatment of intercurrent illnesses should be started.

Antileishmanial Drugs

Pentavalent antimonials (Sb^{V}) Sodium stibogluconate (100 mg/mL) and meglumine antimoniate (85 mg/mL) at the dose of

20 mg/kg body weight for 28–30 days has been the standard treatment for VL in most parts of the world. However, due to extensive drug resistance to Sb^{V} in Bihar, where the cure rate fell to less than 50%, it has been replaced by other drugs. Some common adverse events of Sb^{V} are metallic taste in mouth, arthralgia, myalgia, elevated hepatic and pancreatic enzymes. Cardiotoxicity—prolongation of QTc of more than 0.5 sec is an ominous sign, and may culminate into life-threatening cardiac arrhythmias. Antimonials are more toxic in HIV patients and a significant proportion of them have chemical pancreatitis.

Amphotericin B (AmB) It is a polyene antibiotic which is used for the treatment of antimony resistant VL in Bihar, India. It has excellent cure rates (~ 100%) at doses of 0.75–1.0 mg/kg for 15 days administered either daily or on alternate days. Adverse effects are very common include infusion reactions like high fever with rigor and chills, nausea, vomiting, thrombophlebitis. Serious and occasionally life-threatening adverse events include nephrotoxicity, hypokalemia and rarely hypersensitivity reaction, myocarditis, and bone marrow suppression.

Lipid formulations of AmB are rapidly picked up by the reticuloendothelial tissues, thus the amount of free drugs available is low leading to significantly decreased toxicity. This permits administration of large doses of the drug over a short period. Liposomal amphotericin B (AmBisome®; Gilead Sciences, USA; L-AmB), is the only US Food and Drug Administration approved AmB lipid formulation for VL. The total dose requirements of lipid formulations for treatment of VL vary from region to region. In India and Bangladesh, a single dose of 10 mg/kg results in a cure rate of more than 95%, and is currently one of the preferred treatments for VL in this region. In the Mediterranean region, Africa and South America a total dose of 18–21 mg/kg has been recommended. Recent studies suggest that L-AmB is not very effective in Sudanese patients.

Miltefosine An alkyl phospholipid, is the first oral antileishmanial agent, and is available as 10 mg and 50 mg capsules. It is registered for use in India since 2002 for the treatment of VL. It is the chosen drug for the VL elimination program in the Indian subcontinent (India, Nepal and Bangladesh). The recommended dose for children between 2 years and 11 years is 2.5 mg/kg for 28 days, for children 12 years and above 50 mg daily for those weighing less than 25 kg and 50 mg twice daily for those more than 25 kg for 28 days after meals. Cure rate is 94% in Indian children.

Adverse events include vomiting and diarrhea in 40% and 20% patients, respectively, and there may be asymptomatic elevation of liver enzymes. Rarely nephrotoxicity may occur. It has teratogenic potential and thus women of childbearing potential have to observe contraception for the duration of treatment and for an additional 3 months, due to its long half-life of approximately one week. Its long half-life also makes it vulnerable to the development of drug resistance. In a recent study from India, the efficacy of miltefosine appears to have declined and the relapse rate has doubled as compared to 2002. Efficacy of miltefosine in Nepal has been reported to be only 73%.

Paromomycin (PM, aminosidine) Paromomycin is an aminoglycoside-aminocyclitol antibiotic approved by the Indian government in 2006 for the treatment of VL. It should be used at a dose of 11 mg base/kg intramuscular (IM) injection daily for 21 days. It has a cure rate of 95% in the Indian subcontinent. The dose in other endemic regions has not been established. Pain at the injection site is the most common adverse event, whereas a small proportion of patients develop ototoxicity and rise in hepatic transaminases, both of which are completely reversible. Nephrotoxicity is rare. There is no data regarding its use in pregnancy. The main advantage of the drug is its low cost.

Multidrug Therapy

With growing resistance to antileishmanials, multidrug therapy is likely to be preferred in the future. The advantages are:

- Increased activity through use of drugs with synergistic or additive activity acting at different sites
- Shorter duration of therapy
- Lower dose requirement of individual drugs thereby decreasing toxicity and cost
- Preventing the emergence of drug resistance.

In a recent phase III study from India, single infusion of 5 mg/kg of L-AmB with either 7-day oral miltefosine or 10-day IM paromomycin; or 10 days each of miltefosine and paromomycin (with similar daily dose as in monotherapy) had excellent cure rates (>97% in all arms). In East Africa, the combination of sodium stibogluconate at 20 mg/kg plus paromomycin given at 15 mg/kg (11 mg base) for 17 days has shown excellent efficacy.

Treatment Guidelines

There are regional variations in dosage and duration of antileishmanial drugs. While a single dose of 10 mg/kg of L-AmB or combination therapy are the preferred treatment options in the Indian subcontinent, a combination of sodium stibogluconate with paromomycin for 17 days is treatment of choice in East Africa and Yemen. For Mediterranean Basin, Middle East, Central Asia and South America, L-AmB at a total dose of 18–21 mg/kg is recommended.

Post-Kala-azar dermal leishmaniasis In India, miltefosine for 12 weeks or amphotericin B 60–80 doses over 4 months are the recommended regimens for PKDL. In East Africa, PKDL is not routinely treated, as the majority of cases (85%) heal spontaneously within 1 year. Only patients with severe or disfiguring disease, those with persistent lesions (>6 months) or concomitant anterior uveitis and young children with oral lesions that interfere with feeding are treated. Sodium stibogluconate (20 mg/kg/day) for up to 2 months or a 20-day course of L-AmB at 2.5 mg/kg/day are used for these patients.

HIV-VL coinfection Liposomal AmB is the drug of choice for HIV-VL coinfection. A dose of 3–5 mg/kg/day intermittently for 10 doses (days 1–5, 10, 17, 24, 31 and 38) up to a total dose of 40 mg/kg is recommended but relapse is common. Secondary prophylaxis with L-AmB (5 mg/kg) every 3 weeks has been found to be useful in decreasing relapses. If L-AmB is not available, amphotericin B deoxycholate can be used. Antiretroviral therapy should be initiated immediately.

CUTANEOUS LEISHMANIASIS

Cutaneous leishmaniasis is caused by various *Leishmania* species. Up to 90% of cases of CL occur in Afghanistan, Algeria, the Islamic Republic of Iran, Saudi Arabia, the Syrian Arab Republic, Bolivia, Brazil, Colombia, Nicaragua and Peru. Based on its geographical distribution, CL can be divided into Old World (including southern Europe, the Middle East, parts of southwest Asia and Africa) and New World leishmaniasis (from Mexico and Latin America).

Old world CL is caused mainly by *L. infantum*, *L. tropica*, *L. major* and *L. aethiopica*. *L. tropica* causes anthroponotic CL and is found in areas ranging from western India to Turkey and parts of North and East Africa. *L. major* causes zoonotic CL in western and central Asia, North and sub-Saharan Africa, Kazakhstan, Turkmenistan and Uzbekistan where Nile rats, rodents and gerbils are the reservoir. *L. aethiopica* is endemic in Ethiopia, Uganda and Kenya, and causes zoonotic CL as well as diffuse cutaneous leishmaniasis (DCL) with hyraxes as their reservoir. *L. infantum* causes zoonotic CL in the Mediterranean Basin, Middle East,

Central Asia and China with dog as a reservoir. Cases of CL due to *L. donovani* have been reported from Cyprus, Israel and Sri Lanka.

New World leishmaniasis (from Mexico and Latin America) is caused predominantly by *L. mexicana* complex consisting of *L. amazonensis*, *L. mexicana*, *L. pifanoi* and subspecies *Viannia* consisting of *L. (V.) peruviana*, *L. (V.) guyanensis*, *L. (V.) panamensis*, and *L. (V.) braziliensis*.

Immunopathogenesis

In most patients T_H1 response results in asymptomatic or subclinical infection however it can lead to ulcerative skin lesions in some individuals. In those with skin lesions CD4 and CD8 T-cell IFN- γ and TNF- α producing lymphocytes, macrophages and B-cells constitute the majority of infiltrating cells. IL-10 and IL-13 have been associated with chronic lesions.

During active destruction of parasites in the skin there is edema in the superficial dermis and damage to collagen and elastin, with an increase in reticulin, followed by fibrosis.

Clinical Features

At the site of sandfly bite a papule or nodule appears after a few days or weeks which grow slowly. A crust then forms over it which may fall away, leading to an ulcer up to 5 cm in diameter with a raised edge and variable surrounding induration (**Fig. 5**). Small satellite lesions may develop just outside the ulcer or plaque. The lesions may be single or multiple and heal gradually over 2–15 months leaving a pigmented scar. Lymph node enlargement can occur. Lesions due to *L. major* and *L. mexicana* heal faster as compared to *L. tropica* and subspecies *Viannia*.

L. tropica can cause a chronic form of CL called leishmaniasis recidivans, also known as lupoid or tuberculoid leishmaniasis that may last for many years. New scaly erythematous papules and nodules arise in the center or periphery of a healed lesion. Skin biopsy demonstrates few parasites, but with a robust granulomatous, cell-mediated immune response. Untreated, the disease is destructive and disfiguring.

Lesions on the ear called chiclero ulcer (**Fig. 6**) is a self-healing sore caused by *L. mexicana*. *L. aethiopica* can at times give rise to oronasal leishmaniasis, which may distort the nostrils and lips.

Diagnosis

Demonstration of amastigotes from slit skin smears, aspirates, biopsies is the gold standard. Culture from a biopsy sample can be

Figure 5 A patient with cutaneous leishmaniasis with two ulcers with elevated margins and inflammation in and around the ulcers

Figure 6 A patient with chiclero ulcer with extensive lesions on the ear

done. PCR based detection of parasite nucleic acids improves the diagnostic sensitivity and allows identification of the *Leishmania* species. Speciation is particularly important in regions where several *Leishmania* species coexist as there is species specific variation in clinical outcomes and responses to treatment. CL needs to be differentiated from cutaneous tuberculosis, leprosy, fungal infections and malignant ulcers.

Treatment

Treatment recommendations of CL vary according to the infecting species and geographical region. For old world CL, local wound care with careful follow-up are indicated and spontaneous healing occurs in most patients. However, in persistent lesions local therapy is indicated, but if the patient has multiple lesions; large ulcers (≥ 5 cm in diameter); lesions over face, joints, toes, fingers, disfiguring lesions, systemic therapy is given. Patients with HIV coinfection also receive systemic therapy (**Box 1**). In the New World CL, self-healing is less common and some may develop diffuse disease thus antileishmanial treatment is usually given. CL caused by species associated with mucosal leishmaniasis (subgenus *Viannia*—*L. braziliensis* and *L. panamensis*), are given systemic therapy (**Box 2**).

Diffuse Cutaneous Leishmaniasis

Diffuse cutaneous leishmaniasis (DCL) is rare in children, and is a severe and rare form of CL caused by *L. aethiopica* in Ethiopia, *L. mexicana* and *L. amazonensis* in South and Central America. DCL is characterized by abundant parasites in the lesions with low or absent cell-mediated immune responses and an absence of delayed hypersensitivity to leishmanin skin test antigen. Patients have low or absent IFN- γ production by peripheral blood mononuclear cells and high concentrations of TNF- α , IL-10, IL-4, transforming growth factor β (TGF- β). It is characterized by widely disseminated cutaneous macules, papules, nodules or plaques, and by diffuse infiltration of the skin, especially on extensor surfaces of the limbs and on the face, where thickening of the eyebrows and ear lobes may resemble lepromatous leprosy. There is no ulceration. Mucosal involvement is confined to the borders of the nostrils and lips. This disease does not heal spontaneously, and relapses are frequent after treatment.

Mucocutaneous Leishmaniasis

Mucocutaneous leishmaniasis (MCL) is a disease of adults and extremely rare in children. It is caused by New World *Leishmania*

BOX 1 Recommended treatment regimens for Old World cutaneous leishmaniasis (CL) with grade of evidence (not ranked by preference)

Local therapy

• *L. major*:

- 15% PM/12% methylbenzethonium chloride (MBCL) ointment BID for 20 days (A)
- Intralesional antimonials, 1–5 mL per session plus cryotherapy (liquid nitrogen: 195°C), both every 3–7 days (1–5 sessions) (A)
- Thermotherapy, 1–2 sessions with localized heat (50°C for 30 sec) (A)
- Intralesional antimonials or cryotherapy independently, as above (D)

• *L. tropica*, *L. aethiopica** and *L. infantum**

- 15% PM/12% MBCL ointment, as above (D)
- Intralesional antimonials plus cryotherapy, as above (D)
- Thermotherapy, as above (A)
- Intralesional antimonials, alone, as above (B)
- Cryotherapy, alone, as above (C)

Systemic therapy

• *L. major*:

- Fluconazole, 200 mg/day oral for 6 weeks (A)
- 20 mg Sb^v/kg/day intramuscularly or intravenously for 10–20 days (D)
- 20 mg Sb^v/kg/day intramuscularly or intravenously plus pentoxifylline, 400 mg TID for 10–20 days (A)

• *L. tropica* and *L. infantum**

- 20 mg Sb^v/kg/day intramuscularly or intravenously for 10–20 days (D)
- 15–20 mg Sb^v/kg/day intramuscularly or intravenously for 15 days plus oral allopurinol 20 mg/kg for 30 days, to treat *L. recidivans* caused by *L. tropica* (C)

• *L. aethiopica*:

- 20 mg Sb^v/kg/day intramuscularly or intravenously plus PM, 15 mg (11 mg base)/kg/day intramuscularly for 60 days or longer to treat diffuse CL (C)

Abbreviations: Sb^v, pentavalent antimonials; PM, paromomycin.

Source: Control of the leishmaniasis. Report of a meeting of the WHO Expert Committee on the Control of Leishmaniases, 22–26 March 2010. WHO Technical Report Series 949. Grade A is the highest level of evidence.

*Few data are available on therapy for CL caused by *L. infantum* and *L. aethiopica*.

of subgenus *Viannia*—*L. braziliensis* and *L. panamensis* and rarely by *L. guyanensis* and *L. amazonensis*. Most cases are reported in Bolivia, Brazil and Peru. It is characterized by strong T_H1 response with high levels of IFN- γ and TNF- α , and strong delayed type hypersensitivity to leishmanin skin test. Intense inflammation causes extensive destruction of the tissues (**Fig. 7**). It can occur either simultaneously with cutaneous lesion or years later. It involves the mucosal tissues of the mouth and upper respiratory tract by lymphatic or hematogenous dissemination. Nasal lesions start with nodules and infiltration of nasal cartilage leading to obstruction and perforation. Mutilation of pharynx and larynx can also occur if left untreated. Local lymphadenopathy is frequent. MCL never heals spontaneously. Secondary bacterial infections are frequent, intercurrent pneumonia is the most common cause of death. Parasites are scarce in the lesional tissues and demonstration of parasite DNA by PCR is more sensitive.

Treatment of choice is pentavalent antimonials at the dose of 20 mg/kg for 30 days. Adding oral pentoxifylline at 400 mg/8 hour (in adults) to pentavalent antimonials for 30 days reduces the healing time significantly. Amphotericin B deoxycholate: 0.7–1 mg/kg by infusion every other day up to 25–45 doses can be given in relapsed cases. Liposomal amphotericin B at the dose of 2–3 mg/kg daily by infusion up to a total dose of 40–60 mg/kg is also considered adequate. In Bolivia, miltefosine at 2.5 mg/kg per day

BOX 2 Recommended treatment regimens for New World cutaneous leishmaniasis (CL) with grade of evidence

- Local therapy (all species)
 - 15% PM and 12% MBCL ointment BID for 20 days (B)
 - Thermotherapy: 1–3 sessions with localized heat (50°C for 30 sec) (A)
 - Intraleisional antimonials: 1–5 mL per session every 3–7 days (1–5 infiltrations) (B)
- Systemic therapy
 - *L. mexicana*
 - Ketoconazole: adult dose, 600 mg/day oral for 28 days (B)
 - Miltefosine: 2.5 mg/kg/day orally for 28 days (B)
 - *L. guyanensis* and *L. panamensis*
 - Pentamidine isethionate, intramuscular injections or brief infusions of 4 mg salt/kg/dose every other day for 3 doses* (C)
 - 20 mg Sb^v/kg/day intramuscularly or intravenously for 20 days* (C)
 - Miltefosine: 2.5 mg/kg/day orally for 28 days (B)
 - *L. braziliensis*
 - 20 mg Sb^v/kg/day intramuscularly or intravenously for 20 days (A)
 - Amphotericin B deoxycholate: 0.7 mg/kg/day, by infusion, for 25–30 doses (C)
 - L-AmB: 2–3 mg/kg/day, by infusion, up to 20–40 mg/kg total dose (C)
 - *L. amazonensis*, *L. peruviana* and *L. venezuelensis*
 - 20 mg Sb^v/kg/day intramuscularly or intravenously for 20 days
- Relapse treatment
 - Amphotericin B deoxycholate, as above
 - Sb^v: As above plus topical imiquimod every other day for 20 days (A)
 - L-AmB: 3 mg/kg/day, by infusion, up to 20–40 mg/kg total dose may be considered

Abbreviations: Sb^v, pentavalent antimonials; L-AmB, liposomal amphotericin B; PM, paromomycin.

*The efficacy of pentamidine and Sb^v depends on the geographical area.

Source: Control of the leishmaniasis. Report of a meeting of the WHO Expert Committee on the Control of Leishmaniases, 22–26 March 2010. WHO Technical Report Series 949. Grade A is the highest level of evidence.

Figure 7 A patient with mucocutaneous leishmaniasis with extensive destruction of the nasal septum

orally for 4–6 weeks gives a cure rate of 70%. High cure rates are obtained when the disease is mild and lesions are limited to the nose and mouth. However, relapse and recurrence are frequent after clinical improvement and apparent cure when the larynx, vocal cords and trachea are involved. Thus regular follow-up of MCL, even after treatment which includes nasopharyngeal and laryngeal visualization, is essential.

PREVENTION

No vaccine is available for leishmaniasis. As prior infection confers some immunity against the infecting *Leishmania* species, leishmanization as a strategy is used in regions at risk for *L. major* infection. It consists of injecting viable parasites to produce a controlled skin lesion and induce T-cell immunity. Insecticide treated collars for dogs, vaccination and treatment of domestic dogs and culling of street dogs have been used to reduce *L. infantum* infection. Personal prophylaxis like protective clothing (as sandfly cannot penetrate clothes), use of insect repellent and bed nets are protective. Anthroponotic leishmaniasis is controlled by early case finding, treatment and vector control with residual insecticide spraying and use of insecticide impregnated bed nets.

IN A NUTSHELL

1. Leishmaniasis occurs in 98 countries throughout the world and in three major forms.
2. K39 antigen based rapid diagnostic tests are increasingly being used for the diagnosis of visceral leishmaniasis.
3. In Indian subcontinent liposomal amphotericin B or multidrug therapy are preferred treatment for visceral leishmaniasis; whereas in East Africa a 17-day combination therapy of pentavalent antimonials and paromomycin is the best option.
4. Liposomal amphotericin B is preferred in the Mediterranean region and for HIV-VL coinfection.
5. Liposomal amphotericin B, pentavalent antimonials or amphotericin B deoxycholate are the drugs recommended for New World VL.
6. Cutaneous leishmaniasis: Diagnosis is based on demonstration of amastigotes in tissue scrapings and speciation. Treatment varies with species and regions. Local treatment is preferred in old World cutaneous leishmaniasis.

Chapter 32.4

Amebiasis

Piyush Gupta, Aashima Dabas

Amebiasis is caused by the protozoa *Entamoeba histolytica* and usually presents with dysentery or diarrhea. The ameba may spread to various organs, the commonest being the liver where it manifests as amebic liver abscess. *E. histolytica* can be differentiated antigenically and by molecular methods from *Entamoeba dispar* which is nonpathogenic and responsible only for asymptomatic infection.

EPIDEMIOLOGY

E. histolytica has a worldwide distribution and is endemic in developing countries due to low socioeconomic conditions. It is the third leading cause of parasitic death in the world after malaria and schistosomiasis. It is estimated that approximately 10% of the world's population, i.e., 600 million people are infected, with an annual mortality of 40,000–110,000. Prevalence rates vary widely with the population studied, from around 1% in the industrialized nations to 50–80% in the tropics. The exact number of persons infected by pathogenic strains is still not clear but from the data available from a few such reports, the asymptomatic carriage seems to predominate with a prevalence of 10% and only 1% for pathogenic strains. In India, the prevalence rates vary from 5%–50% depending upon the population and geographical region.

ETIOLOGY

E. histolytica exists in nature in two forms: (i) cyst or (ii) a trophozoite (**Figs 1A and B**). Cysts are oval or round, asymmetrical with four nuclei. They are easily destroyed by most disinfectants and by heating to 55°C but may survive chlorination of water and in water at low temperature. Cyst is the infective stage of the parasite. Asymptomatic human cyst carriers are the principal reservoir of infection. There is no animal reservoir.

MODE OF SPREAD

The infection is transmitted by ingestion of food or water contaminated with fecal material containing cysts of *Entamoeba*. The source of contamination may be the food handlers or flies. The infective dose is less than 10 cysts. Cysts can remain viable and infective in water (even after chlorination) and feces for several days. They are thus potential agents for bioterrorism. Sexual transmission is also reported.

Young, immunocompromised and malnourished children and those receiving steroids are at a higher risk of severe *E. histolytica* infection. Other factors contributing to increased transmission

include low socioeconomic status, overcrowding, lack of piped water supply and poor sanitation. Recent research has shown increased genetic susceptibility to amebiasis in those with mutations of leptin receptor. Some protection is seen in children possessing the DQB1*0601 HLA allele genotype.

PATHOGENESIS

Following ingestion, cyst hatches in the small intestine to produce eight trophozoites. Trophozoites colonize and adhere to the colonic mucosa through a galactose and N-acetyl-D-galactosamine (Gal/GalNAc)-specific lectin which attaches to host cell receptors. This interaction generates a protective mucosal secretory IgA response. The trophozoites are also capable of inducing cytotoxicity of target cells or lymphocytes by introducing channels known as amebapores which are responsible for perforin mediated lysis. The protozoan has abundance of cysteine proteases which cause degradation of extracellular matrix of the host. The trophozoites multiply and spread laterally underneath the intestinal epithelium producing characteristic *flask-shaped or teardrop ulcers*. These lesions are commonly found in cecum, transverse colon and sigmoid colon. There is little local inflammatory response. Some ameba trophozoites become cyst and are passed in the stool to survive for weeks in a moist environment. On the other hand, some trophozoites invade the intestinal mucosa and spread via bloodstream to the liver, lung and brain.

Extraintestinal Complications

They arise from spread of infection through portal circulation. Amebic liver abscess forms because of toxin release and hepatocyte damage. It is seen more frequently in the right lobe of the liver (posterosuperior part); 5–20% have abscess in the left lobe. Single liver abscess is found in 95% of instances. Its contents are chocolate colored and viscid (described as anchovy-sauce appearance), usually sterile, and contain no neutrophils. Amebae are located at the periphery of abscess. The abscess may regress, rupture or disseminate. Transdiaphragmatic rupture of liver abscess into the pleural space may result in amebic empyema and pulmonary amebiasis. The abscess may also rupture into the peritoneum (2–5%) or pericardial cavity (<1%).

CLINICAL FEATURES

E. histolytica infection is asymptomatic in 90% of patients. About 4–10% of persons infected with *E. histolytica* develop amebic colitis, while less than 1% develop disseminated disease including amebic liver abscess. The intestinal involvement can result in acute illness like dysentery or bloody diarrhea, fulminating colitis, amebic appendicitis and ameboma of the colon.

Intestinal Disease (Amebic Colitis)

Incubation period for symptomatic disease varies from 2 weeks to months. Acute intestinal amebiasis presents with colicky abdominal pain, tenesmus and frequent loose stools containing mucus and blood. The stool may be positive for occult blood. Fever is seen in only one-third of patients and constitutional symptoms are rare (unlike bacillary dysentery). Examination may reveal diffuse tenderness in the cecal or rectosigmoid junction areas. The course of illness may be protracted lasting for weeks or even months. Rarely, a reactive collection of edematous granulation and fibrous tissue called an ameboma can grow into the lumen causing pain, obstruction and possibly, intussusception. Chronic amebiasis presents with intermittent diarrhea is often followed by constipation due to spasm of the large intestines, fatigue and weight loss. Toxic megacolon, pneumatosis coli (intramural air) and peritonitis can also occur. Acute amebic dysentery should

Figures 1A and B *Entamoeba histolytica*. (A) Cyst; (B) Trophozoite

be differentiated from that caused by *Shigella*, *Salmonella*, *Campylobacter*, *E. coli* and *Yersinia*.

Amebic Liver Abscess

It develops in less than 1% of infected persons, often months to years after exposure. A past history of amebic dysentery is forthcoming in only 20% of patients and only 10% have concomitant intestinal symptoms. The child presents with high fever with chills and rigors, abdominal pain, distension and tender hepatomegaly, and appears toxic. Pain in the upper abdomen is intense and radiates to the shoulder. Jaundice is uncommon and observed in only 10–15% cases. Abscess may rupture into pleural space, peritoneum and pericardium requiring emergency drainage. Mortality in children in ruptured abscess can be up to 25%. (refer Section 37 for further details on amebic liver abscess).

INVESTIGATIONS

Parasite Detection

Microscopic examination of formed stool for cysts or diarrheal stool for trophozoites is necessary for the diagnosis of intestinal infection with *E. histolytica*. Diarrheal stools must be examined within 1 hour of collection to look for motility of trophozoites. Stool microscopy cannot distinguish *E. histolytica* from *E. dispar* infection unless phagocytosed erythrocytes are seen in trophozoites (seen in *E. histolytica*). Stool antigen testing may also distinguish the two species. A complete examination of stool for cysts includes wet mount in saline, an iodine-stained wet mount and a fixed trichrome-stained preparation. Fixation of the smear is recommended as the trophozoites degenerate in unfixed smears. The stained preparations not only delineate cyst morphology but also distinguish bacillary from amebic dysentery. Stool contains plenty of erythrocytes but few leukocytes in patients with amebic colitis unlike bacillary dysentery where the inflammatory cells, especially polymorphonuclear cells are replete. Other stains like Giemsa, methylene blue, Ziehl-Neelsen or Wright stains can also be used as they delineate the nucleus well. At least three stool specimens taken on consecutive days should be examined to exclude amebic infection of the intestines since excretion of cysts may be intermittent. However, detection of amebic cysts, even with associated gastrointestinal symptoms does not necessarily indicate acute infection. Moreover, presence of contaminants, lack of expertise in detection by microscopy and delay in transport and processing the stool sample decrease the reliability of stool microscopy alone for diagnosis.

Few culture media have been used for isolation like Locke-egg media or TYI-S-33. The isoenzyme analysis is considered as *gold standard* which is done on culture samples and can differentiate pathogenic and nonpathogenic amebae. The culture yield is however unsatisfactory in most cases as maintenance of a protozoan culture is tedious and mixed growths are commonly encountered.

Serology

The usefulness of serological tests in intestinal amebiasis is limited due to high seropositivity rates in endemic areas. In extraintestinal amebiasis and invasive amebiasis, antibody detection by enzyme-linked immunosorbent assays (ELISA) is the most sensitive test. The detection of IgM is suggestive of recent amebiasis unlike IgG response. Indirect hemagglutination (IHA) test may be done for invasive intestinal disease or liver abscess which has shown good results in immunocompromised individuals. IHA is usually negative in asymptomatic carriers. Serological response as detected by counterimmunoelectrophoresis (CIE) or ELISA becomes negative 6–12 months after infection. IHA, on the other

hand, may stay positive for as long as 10 years following complete recovery. Recently, antigen based ELISA kits have been used for detection which have excellent sensitivity and specificity. These kits can differentiate *E. histolytica* from *E. dispar*. The kits are coated with monoclonal antibodies targeted against the serine-rich residue or Gal/GalNAc-specific lectin of *E. histolytica*. Besides detection in stools, the kits can also be used for detection of antigen in saliva, serum or abscess fluid. The only limitation of the kit is that it can be applied only on fresh samples and renders fixed smears unsuitable. Molecular based polymerase chain reaction (PCR) stool assays (conventional and real-time PCR) have been used in research settings. Their performance is affected by lack of uniformity, stringent temperature and transport requirements for DNA extraction and high chances of false-negative results due to contamination. A triage parasite panel impregnated with monoclonal antibodies against *Giardia*, *Cryptosporidium* and *Entamoeba* has also been developed. It is simple, convenient and has shown greater than 95% sensitivity and specificity on unfixed, fresh stool samples. However, it fails to differentiate between *E. histolytica* and *E. dispar*. **Table 1** shows the comparative performances of various diagnostic methods in intestinal amebiasis.

Imaging

Sigmoidoscopy followed by aspiration of mucosal lesions or biopsy is valuable in symptomatic sick patients where other tests fail to provide conclusive evidence.

Liver Aspirate

It is difficult to demonstrate the amebae in the liver aspirate. Trophozoites are sparse in the aspirate and can be demonstrated only from the wall of the abscess.

Others

Leukocytosis, anemia, high erythrocyte sedimentation rate (ESR) and elevated alkaline phosphatase are common in amebic liver abscess. There is no eosinophilia in invasive disease.

TREATMENT

Due to the possibility of its invasive nature and severe extraintestinal manifestations, all children with *E. histolytica* infection, whether symptomatic or not, should be treated. Luminal amebicides, such as diloxanide furoate and iodoquinol, act on only those organisms that are present in the intestinal lumen. Tissue amebicides, such as metronidazole, tinidazole, chloroquine and dehydroemetine, are effective in the treatment of invasive amebiasis but are less effective for luminal clearance. A combination of a luminal and a tissue amebicide is thus advocated for complete parasite clearance in invasive disease. Metronidazole is the most popular drug for management of both intestinal and extraintestinal forms of

Table 1 Diagnostic tools for intestinal amebiasis

Diagnostic method	Sensitivity	Specificity
Stool microscopy	<60%	10–50%
Serum antibody (ELISA)	>90%	>85%
Serum antigen (ELISA)	65%	>90%
Stool antigen (ELISA)	>95%	>95%
Stool PCR	>70%	>90%

Abbreviations: ELISA, enzyme-linked immunosorbent assays; PCR, polymerase chain reaction.

Adapted from Tanyuksel M, Petri WA. Laboratory diagnosis of amebiasis. Clin Microbiol Rev. 2003;16(4):713–29.

amebiasis, and till date there is no evidence of resistance against this agent.

Invasive amebiasis (both intestinal and extraintestinal) should be treated initially with a tissue amebicide like: (i) oral metronidazole 35–50 mg/kg/day in three divided doses for 7–10 days or (ii) tinidazole 50 mg/kg/day once daily for 3–5 days. Tinidazole is as efficacious as metronidazole but the treatment duration is shorter with fewer adverse effects. Following this all children should be given a course of luminal amebicide: (i) diloxanide furoate 20 mg/kg/day in three divided doses for 7 days, (ii) paromomycin 25–35 mg/kg/day in three divided doses for 7 days or (iii) iodoquinol 30–40 mg/kg/day in three divided doses for 20 days. Either of paromomycin, diloxanide furoate or iodoquinol may be used to treat asymptomatic carriers, given in the regimen same as for invasive disease. Reinfection is quite common even after complete cure. For cases of *fulminant amebic colitis*, therapy with dehydroemetine (1 mg/kg/day subcutaneously or IM), may be instituted. Broad spectrum antibiotics may also be needed. Intestinal perforation or ruptured amebic liver abscess or toxic megacolon may warrant surgical intervention.

PREVENTION

Prevention involves avoiding fecal contamination of food and water and adopting good handwashing technique. Boiling and purification of drinking water by filtration is an important preventive measure. The use of night soil (human feces) for fertilization of crops should be avoided.

AMEBIC MENINGOENCEPHALITIS

There are three genus of free living amebae which are implicated in human disease namely: *Naegleria*, *Acanthamoeba* and *Balamuthia*. The former is associated with rapidly progressive acute meningoencephalitis while the illness caused by the latter two runs a more indolent course.

Primary Amebic Meningoencephalitis

Naegleria fowleri is the causative agent of primary amebic meningoencephalitis (PAM) which is characterized by a rapidly progressive fatal course. The parasite resides in warm water. The life cycle includes two forms: (i) trophozoite and (ii) cyst. The infection is frequently acquired from contaminated swimming pools or lakes and reaches the brain via the olfactory epithelium of the nose. Histological changes in the brain include edema, hemorrhage, necrosis and hyperemia of meninges. There is purulent exudate throughout the brain parenchyma, more so over the gray matter. The incubation period is short (2–7 days) which is followed by fever, malaise, seizures and signs of meningoencephalitis. The clinical presentation closely resembles that of acute pyogenic meningitis. The survival rates are poor due to severity of illness and difficulty in establishing a timely diagnosis. The cerebrospinal fluid (CSF) shows neutrophilic predominance, elevated proteins and reduced sugar levels. The diagnosis is confirmed by demonstration of motile trophozoites on a wet mount of CSF (which may be mistaken for atypical mononuclear cells). Molecular diagnostic techniques may also be used in high cases of suspicion. Imaging is seldom helpful as it may show nonspecific changes or mild edema with basilar meningeal enhancement. The disease is fatal in most cases. As per data from Centers of Disease Control and Prevention (CDC), the mortality rate of PAM was 129/132 cases in US alone from 1962–2008. Amphotericin-B, rifampicin and fluconazole have been used for treatment. Steroids have been tried in some patients with undefined benefit. Miltefosine is recently approved by CDC for treatment of free living amebae. Among the very few survivors, sequel like hydrocephalus and delayed development has been noted.

Granulomatous Amebic Meningoencephalitis

Granulomatous amebic meningoencephalitis (GAM) is caused by *Acanthamoeba*, a ubiquitous ameba found in soil, dust, untreated or distilled water, swimming pools and other domestic environments. The organism derives its name by the virtue of presence of spike-like structure (acanthopodia) on its surface. Almost 20 species of *Acanthamoeba* are known which are subgrouped into three groups. Organisms of group II are most abundant and most pathogenic to humans. *Acanthamoeba* is frequently associated with keratitis in immunocompetent hosts, especially among contact lens users. Besides keratitis, it also causes subacute granulomatous dermatitis, sinusitis, pneumonitis, disseminated disease and a chronic meningoencephalitis which has been described as granulomatous amebic encephalitis (GAE) due to its histological picture. GAE is a rare and fatal illness which is commonly seen in immunocompromised individuals. Almost 1.57 deaths per 10,000 HIV/AIDS deaths have been attributed to GAE. The organism exists in two forms: (i) active trophozoite and (ii) a dormant cyst stage. Their virulence is predominantly due to release of proteases. The most common portal of entry is the respiratory route which results in hematogenous spread in immunocompromised individuals. The clinical presentation and course of GAE is almost similar to tubercular meningitis. Another differential diagnosis to be considered is cryptococcal meningitis. The CSF picture is also similar showing elevated proteins and lymphocytic pleocytosis. The diagnosis of GAE is confirmed by demonstration of trophozoites in CSF. In vivo confocal microscopy or examination of contact lenses can be done for detection of *acanthamoeba* keratitis. Alternately, immunofluorescence assays and multiplex real-time PCR are also available, though their use is limited by cost and availability. Serological tests may be used to identify antiacanthamoeba antibodies. Imaging of the brain may detect ring-enhancing, space-occupying lesions in GAE. The treatment is largely empirical as no specific drug therapy has been found useful. The treatment options include drugs like pentamidine, flucytosine, ketoconazole and amphotericin B. A combination of voriconazole and miltefosine has shown promising results. Both these drugs have good central nervous system (CNS) penetration and better safety profiles.

Balamuthia Mandrillaris

Balamuthia mandrillaris is a free living ameba implicated in meningoencephalitis which presents as a subacute or chronic illness. The disease is rare, affects children and elderly and is difficult to diagnose. The disease is seen among transplant patients also. The protozoan is found in soil and water and is transmitted by contamination of skin wounds or by aspiration. It commonly results in painless skin ulcers, chronic sinusitis and pneumonia. The trophozoites can spread hematogenously to CNS manifesting as fever, personality changes, headache, focal seizures, cranial nerve or motor deficits. Almost a quarter of such patients have preceding skin lesions at presentation. The detection of trophozoites in CSF is difficult which may reveal only lymphocytic pleocytosis with elevated proteins. Imaging of the brain may show solitary or multifocal mass-like lesions with ring enhancement, edema and hydrocephalus. Trophozoites can be detected in the skin biopsy which show granulomatous inflammation and vasculitis. Molecular diagnostic techniques, like indirect immunofluorescence (IIF), immunohistochemistry (IHC) or PCR, yield better diagnostic results and can differentiate *Balamuthia* from *Acanthamoeba*. A combination of azoles or amphotericin B with a macrolide has shown good survival rates. Other agents which have been tested as efficacious include pentamidine, polymyxin B, albendazole, sulfadiazine, flucytosine and miltefosine. Surgical debulking in case of large lesions is sometimes necessary.

IN A NUTSHELL

1. *E. histolytica* is a common protozoan infecting the humans which frequently causes dysentery.
2. The protozoa may spread hematogenously to result in hepatic abscess.
3. Stool microscopy is the simplest tool to differentiate intestinal amebiasis from bacillary dysentery, but lacks sensitivity and specificity.
4. All infected children should be treated whether symptomatic or not.
5. Treatment of choice is metronidazole. A luminal amebicide should be added for complete eradication.
6. Free living amebae can cause meningoencephalitis in humans either a rapidly progressive acute form (PAM) caused by *Naegleria* or a chronic granulomatous form (GAE) caused by *Acanthamoeba*.
7. Diagnosis of PAM or GAE requires high index of suspicion. Survival depends on timely diagnosis and appropriate therapy.

Chapter 32.5

Giardiasis

Aashima Dabas, Piyush Gupta

Giardia lamblia (also known as *G. intestinalis* or *G. duodenalis*) is an important flagellated protozoan enteropathogen of humans and mammals. It affects 2.5 million people annually and is one of the most common parasite infections of humans worldwide. The clinical manifestations range from asymptomatic carrier state to acute and persistent diarrhea and malabsorption syndrome. There are five other species of *Giardia* namely: (i) *G. agilis*, (ii) *G. ardeae*, (iii) *G. muris*, (iv) *G. microti* and (v) *G. psittaci*, which infect various animals and are nonpathogenic to man.

EPIDEMIOLOGY

According to estimates by the World Health Organization (WHO), almost 1 billion people are infected with giardiasis, of which 25 million die annually. It is now included in the *WHO Neglected Disease Initiative*. The protozoan is a commoner occurrence in developing countries (prevalence rate 20–30%) as compared to the developed countries which report prevalence as less as 2–5%. During giardiasis surveillance from 2006–2008, almost 19,000 new cases were documented by the Centers for Disease Control and Prevention (CDC) in USA alone.

Agent

The parasite exists in the form of trophozoites or cysts (**Figs 1A and B**). Trophozoites colonize the proximal small intestine. Cysts are excreted in the feces; these are the infective stage of the parasite. There are eight genotypic assemblages (A to H) for *G. lamblia*. The human are infected with assemblage A or B while the rest assemblages infect dogs, cats and other household pets. Both A and B genotypes have also been isolated among other mammals.

Host Factors

Children appear to be more severely affected than adults. The infection is generally self-limited in immunocompetent children and adults. Humoral immunodeficiency is associated with chronic *Giardia* infection. Children with undernutrition and cystic fibrosis are particularly predisposed to giardiasis. Breastmilk contains glycoconjugates and secretory IgA that protect against giardiasis.

Children in frequent contact with livestock and other animals also have higher predisposition to infection.

Environmental Factors

Man and contaminated water supply remain the major reservoirs of *Giardia*. Giardiasis is spread by fecal-oral contamination, the prevalence being higher in populations with poor sanitation, close contact, and oral-anal sexual practices. Thus, a seasonal trend toward frequent outbreaks from June to October has been seen. The disease is commonly waterborne because *Giardia* is resistant to the chlorine levels in normal tap water. Foodborne transmission is rare but can occur with ingestion of raw or undercooked foods. There is a risk of zoonotic transmission of *Giardia* reported from dogs, cats and cattle. This transmission has been found bidirectional in some cross-sectional surveys, suggesting the possibility of *reverse zoonosis*, wherein human specific *Giardia* assemblages were isolated from animals.

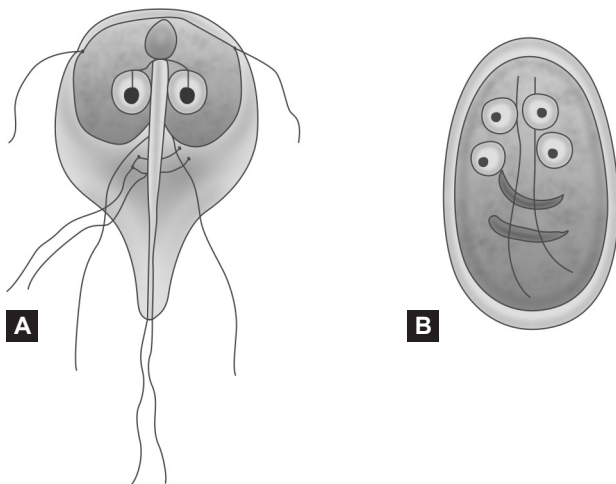

PATHOGENESIS

The life cycle of *Giardia* consists of two stages: (i) the fecal-orally transmitted cyst and (ii) the disease-causing trophozoite. Cysts are passed in a host's feces, remaining viable in a moist environment for months. Ingestion of at least 10–25 cysts can cause infection in humans. When a new host consumes a cyst, the host's acidic stomach environment stimulates excystation. Each cyst produces two trophozoites.

Each trophozoite has four pairs of flagella and two nuclei. The trophozoites carry a ventral disk on its concave surface which enables their attachment to the intestinal wall. These trophozoites migrate to the duodenum and proximal jejunum, where they attach to the mucosal wall by means of a ventral adhesive disk and replicate by binary fission. The flagella of the trophozoite mediate its transport and account for its virulence. In addition to the adhesive disk, the trophozoite also uses complex cytoskeletal contractile network comprised of giardin proteins and microtubular proteins for host cell contact. Growth of trophozoites is promoted by bile, glucose and relative hypoxia. The powerful sucking disk of the trophozoite causes mechanical irritation and damage to the microvilli of the small bowel mucosa resulting in deficiency of brush border enzyme activities. The trophozoite attachment also stimulates an inflammatory cascade by activating intracellular caspases, ultimately resulting in cell apoptosis. This results in malabsorption of sodium and glucose and hypersecretion of chloride which manifests as diarrhea. The trophozoite is capable of wide antigenic variations which help it to evade the host immune system resulting frequently in persistence of infection.

As the detached trophozoites pass through the intestine, they undergo encystation to form oval cysts containing four nuclei. Cysts pass in stools of infected persons and can remain viable for up to 2 months in soil. Unlike amebiasis, there are no invasive or locally destructive lesions in the intestines. The following pathological changes are evident in intestines in giardiasis: intestinal cell apoptosis, crypt hyperplasia, diffuse shortening of brush border and increased mucus production. Functional impairments include intestinal hypermotility, anion hypersecretion, brush border enzyme deficiencies and malabsorption.

Parenchymal involvement of the pancreas has been incriminated for the reported steatorrhea and decreased trypsin activity. Fat malabsorption in giardiasis can also be attributed to bacterial overgrowth in the duodenum and upper jejunum and bile salt deconjugation liberating free bile acids. Immunological studies have shown decreased levels of secretory IgA in duodenal aspirates and depressed T-cell function. Interestingly, prolonged infection with *Giardia* may offer cross-protection against other enteropathogens. It is postulated that repetitive attachment of

Figures 1A and B *Giardia lamblia*. (A) Trophozoite; (B) Cyst

the trophozoite makes the intestinal epithelium unfavorable for attachment by other organisms. In addition, there is activation of host immune responses like secretion of lactoferrin, defensin, secretory IgA and epithelial mucin, which are protective.

CLINICAL FEATURES

Intestinal Giardiasis

Asymptomatic carriage is the most common form of infection. In *symptomatic cases*, incubation period after ingestion of cysts is 1–2 weeks. In *acute infections*, there may be a sudden onset of explosive watery (nonbloody) foul smelling diarrhea along with abdominal distension, flatulence, nausea, anorexia and epigastric cramps. There is no blood or mucus in stools. The illness may last 3 or 4 days and is usually self-limiting in normal immunocompetent children.

Some infections may have a *subacute onset* with a protracted course, with persistent or recurrent mild to moderate symptoms such as brief episodes of loose foul-smelling stools accompanied by flatus and abdominal distension. Between exacerbations, the stools are mushy or there may be constipation. Abnormal stool pattern may alternate with normal bowel movements. Symptoms last for 2–4 weeks.

Thirty to fifty percent children develop *persistent diarrhea*. Children with chronic giardiasis show lactose malabsorption, steatorrhea, iron deficiency anemia and failure to thrive. Unlike *E. histolytica* infection, there is no extraintestinal spread of infection. Giardiasis is also a frequent cause of Traveler's diarrhea (commonest being *Escherichia coli*) where there is history of travel to an endemic country. The diarrhea is prolonged (>7 days) or persistent (≥14 days). A subset of patients may develop long-term complications like postinfectious irritable bowel syndrome and rarely cancer of pancreas or gallbladder.

Extraintestinal Manifestations

Almost one-third of patients suffering with giardiasis may exhibit an extraintestinal complication as enlisted in **Table 1**. The causative mechanisms are still obscure and represent interplay of host and agent factors.

INVESTIGATIONS

Diagnosis is made by examining diarrheal stools for trophozoites or cysts. At least three specimens of stools collected on alternate days (detection rate 90%) are examined microscopically because the multiplication and passage of the giardial cysts is often intermittent. Sensitivity of a single stool examination is only 50%. Stool does not contain blood or leukocytes. Trophozoites are usually seen only in watery diarrhea but can also be detected by endoscopic brush cytology or intestinal biopsy. A duodenal aspirate or biopsy may

yield high concentration of *Giardia*. Biopsy of the duodenum is not routinely recommended but may be done in patients with clinically suspected giardiasis, negative stool tests, negative duodenal fluid aspirate, absent secretory IgA level, hypogammaglobulinemia, abnormal lactose tolerance test or achlorhydria. Another test may be recommended if the microscopic examination of stool is negative, viz. the *string test*. A weighted piece of string is swallowed till it reaches the duodenum. The trophozoites adhere to the string and may be visualized microscopically after withdrawal of the string.

Stool enzyme immunoassay (EIA) or direct immunofluorescence tests for *Giardia* antigens are the preferred tests for diagnosis. Blood cell counts are normal. There is no eosinophilia as there is no tissue invasion. Newer diagnostic tools [polymerase chain reaction (PCR) based] using molecular analysis of small subunit ribosomal RNA (SSU rRNA), *gdh*, *tpi* and *bg* genes of *Giardia* are under development.

TREATMENT

All symptomatic cases—acute and persistent diarrhea, failure to thrive and malabsorption syndrome require drug treatment. Few protocols mention treatment of asymptomatic carriers also. However, due to higher reinfection rates and predisposition to drug resistance in endemic areas, asymptomatic cyst carriers are not treated except during outbreaks.

The following classes of drugs are available for treatment; the doses are summarized in **Table 2**. The drug of choice may be tinidazole or nitazoxanide.

- **5-Nitroimidazoles (5-NI)** These include metronidazole, tinidazole, secnidazole and ornidazole. These drugs chiefly affect the protozoal electron transport. Tinidazole has very high efficacy (>90%) and suffices as a single-dose therapy. However, high cost limits use in mass campaigns. Metronidazole is a cheap and effective alternative. It requires frequent dosing which affects compliance and is associated with side effects like nausea and metallic taste. There is early evidence of carcinogenicity in animal models with use of metronidazole. Few recent reports of drug resistance and rapid reinfection in endemic areas have been reported with its use.
- **Benzimidazoles** Albendazole and mebendazole act by disrupting the tubulin in cytoskeleton of *Giardia*.
- **Nitrothiazolyl-salicylamide derivative** Nitazoxanide inhibits the growth of trophozoites by interfering with enzymes required for anaerobic metabolism. This is a highly effective antiprotozoal drug with limited side effects like abdominal pain and headache. Its safety is not established in infants.
- **Miscellaneous** Furazolidone and quinacrine. Auranofin is a gold containing cysticidal compound, recently approved for use in giardiasis.

Table 1 Extraintestinal complications of giardiasis

System	Complication/manifestation
Ocular	Iridocyclitis, choroiditis, retinal hemorrhages, salt and pepper retinal degeneration
Musculoskeletal	Reactive arthritis or asymmetric synovitis usually of the lower extremities, hypokalemic myopathy, muscle necrosis, chronic fatigue syndrome
Immunological	Predisposition to allergies manifesting as rashes or urticaria
Nutritional	Wasting, undernutrition, stunting, iron deficiency anemia, micronutrient deficiencies
Miscellaneous	Impaired cognitive decline, lower intelligence quotient, poor language cognition and impaired psychomotor development

Table 2 Treatment of giardiasis in children

First-line therapy	
Tinidazole	>3 years: 50 mg/kg, single dose, oral
Nitazoxanide	1–3 years: 100 mg BD for 3 days, oral 4–11 years: 200 mg BD for 3 days, oral >12 years: 500 mg BD for 3 days, oral
Metronidazole	15 mg/kg/day in three divided doses for 5–7 days
Second-line therapy	
Albendazole	>6 years: 400 mg once a day for 5 days
Furazolidone	6 mg/kg/day in four divided doses for 10 days
Quinacrine	6 mg/kg/day in three divided doses for 5 days

Note: Paromomycin is not indicated for treating giardiasis in children.

PREVENTION

The infection can be prevented by adopting safe sanitary practices, regular handwashing and proper disposal of human and animal waste. Since the disease is primarily water borne, contamination of surface water should be minimized and safe potable water should be made available.

IN A NUTSHELL

- Giardiasis is a common parasitic infection of humans.
- It is primarily spread by fecal-oral route through contaminated water supply.
- Clinical spectrum consists of asymptomatic cyst carriers, explosive diarrhea, subacute protracted course with GI symptoms and persistent diarrhea.
- Diagnosis is by stool microscopy of at least three samples; stool EIA is the preferred serological test for detection of *Giardia* antigen.
- Asymptomatic cyst carriers need not be treated routinely.
- Tinidazole or nitazoxamide are the drug of choice for symptomatic cases.

Chapter 32.6

Cryptosporidiosis

Aashima Dabas, Piyush Gupta

Cryptosporidiosis, caused by *Cryptosporidium* spp. primarily presents as watery diarrhea. Children less than 2 years and immunocompromised children, especially those with HIV infection and AIDS are prone to this infection. The organism was first isolated from humans in 1976. The infection is ubiquitous worldwide and higher prevalence rates are seen in developing countries (mean 6.1%) than the developed nations (mean 2.2%).

EPIDEMIOLOGY

Agent

Cryptosporidium is a protozoan parasite of the apicomplexa phylum with 16 species. The two species implicated in human disease are *Cryptosporidium hominis* and *Cryptosporidium parvum*. The former is isolated frequently in human infections in developed countries, while the latter is seen more often in developing countries or in zoonotic infections in developed nations. *C. hominis* results in greater severity of diarrhea and results in more growth faltering than *C. parvum*. The former species is also associated with extraintestinal complications like arthralgia, headache, fatigue and ocular pain, unlike the latter.

Host Factors

The mean prevalence is higher in immunocompromised individuals of both developing countries (24%) and developed countries (14%) than that reported in healthy individuals. Both congenital immunodeficiency states (especially severe combined immunodeficiency syndrome, X-linked hyperimmunoglobulin M syndrome and CD4 lymphopenia) and acquired immunocompromised states like HIV and bone marrow transplant recipients are predisposed to the infection. The prevalence is more in extremes of age-childhood and old-age. Breastfeeding has not shown to be protective. The cell-mediated immunity is the primary defense mechanism; humoral immunity has limited role.

Environmental Factors

Cattle, a known reservoir for *C. parvum*, and has been implicated in various outbreaks. The oocysts are susceptible to desiccation and do not survive well at high temperatures but resistant to routine chlorination of water. Prolonged bright sunlight and exposure to ultraviolet B rays are germicidal. The role of repeated exposures to *Cryptosporidium* spp. in imparting protective immunity to humans is also hypothesized. Higher levels of anti-cryptosporidium antibodies were detected in those with repeated infections.

The Global Enteric Multicenter Study (GEMS) is a 3-year, prospective, age-stratified, case control study conducted in children aged 0–59 months to evaluate the epidemiology of moderate to severe childhood diarrhea, across sub-Saharan Africa and South East Asia at seven sites. *Rotavirus* was the most common isolated microbe, which was closely followed by *Shigella*. Surprisingly, *Cryptosporidium* has been isolated as second most common pathogen at five sites.

PATHOGENESIS

The infection is chiefly acquired by feco-oral route through ingestion of oocysts from contaminated water. Other modes of transmission include person-to-person (outbreaks or at day

care centers and hospitals), food-borne and zoonotic spread. Inhalational mode of transmission has been reported in immunocompromised patients causing laryngotracheitis and mild diarrhea. The infective dose is low—10–83 oocysts for *C. hominis* and 132 oocysts for *C. parvum*. The ingested oocysts excyst in the small intestine and release four sporozoites each. These sporozoites demonstrate gliding motility, during which they deposit various proteins required for attachment and invasion into the host cell. After invasion of enterocytes, a parasitophorous vacuole is formed within the apical cells of intestine. The sporozoites mature into trophozoites which cause modifications of the host actin cytoskeleton of intestinal epithelial cells and alterations in host-cell apoptosis. They divide by asexual reproduction to produce merozoites. Few merozoites may differentiate into gametocytes to form a zygote, which divides by meiosis to produce oocysts. The thin-walled oocysts are implicated in auto-infection and the thick-walled oocysts are excreted to infect other hosts.

CLINICAL FEATURES

The infection presents with nonbloody watery diarrhea following an incubation period of 2–12 days. The symptoms may start even before oocysts are excreted. Vomiting may be seen in more than 80% of infected children. Fever occurs in about 50% of infected children. The disease is usually self-limiting in immunocompetent children, though oocysts may be shed for months, seen as asymptomatic carriage. In immunocompromised patients, severe constitutional symptoms like abdominal cramps, nausea, vomiting, and fever may be observed. They are at risk of more severe and fulminant disease course which may result in death. *Cryptosporidium* frequently results in persistent diarrhea in malnourished children. It may also cause serious affection of the biliary tract and pancreas manifesting as sclerosing cholangitis, acalculous cholecystitis, and/or pancreatitis. Rarely respiratory tract involvement may cause chest infiltrates. The disease is also known to result in psychomotor developmental impairment in long-term. Recent research has highlighted the role of *C. parvum* in colorectal cancer and other cancers of the digestive tract in immunocompromised individuals.

DIAGNOSIS

Infection is detected by microscopic examination of stool using modified acid-fast staining wherein the oocysts appear as small, spherical bodies (2–6 µm). A minimum load of 500,000 cysts per mL is required to detect it by acid-fast staining. At least three stool samples should be examined as shedding of oocysts is intermittent. Moreover, due to the small size of oocysts, they may be missed or may be reported as contaminants in the stool samples. Modified staining methods like fluorescent stain (auramine O) or immunofluorescent stains are more specific stains which improve detection rate.

Detection of *Cryptosporidium* spp. by oocyst antigen capture using ELISA improves the chances of isolation from the stool samples. Newer molecular methods used for detection include PCR, immunofluorescence microscopy, colorimetric in situ hybridization, fluorescent in situ hybridization, and real time quantitative PCR. The applicability of these methods is still in research settings. Biopsy of the intestine may reveal *Cryptosporidium* organisms in the microvillus border especially in the jejunum. Histopathology of the intestine reveals villus atrophy, epithelial flattening and inflammation of the lamina propria.

TREATMENT

The mainstay of treatment is adequate rehydration. Nitazoxanide is the only FDA approved drug for use in cryptosporidiosis. It is to be given for 3 days duration at the following dose—1–3 years: 100

mg BD, PO; 4–11 years: 200 mg BD, PO; and ≥ 12 years: 500 mg BD, PO. The drug is not licensed for use in infants. It is available both in tablet and suspension form. Certain drugs like thymidylate synthase inhibitors (5-fluorouracil) have also shown promising results in research settings. Agents under evaluation for chemoprophylaxis of cryptosporidiosis in children with HIV infection include rifabutin, clarithromycin and hyperimmune bovine colostrums. Research is still ongoing for production of a suitable vaccine.

The most effective strategy for infection containment remains provision of hygienic potable water supply and effective and safe water storage, sanitation and sewage management.

Singh BB, Sharma R, Sharma JK, et al. Parasitic zoonoses in India: an overview. Rev Sci Tech. 2010;29:629-37.

IN A NUTSHELL

1. *Cryptosporidium* is the emerging causative agent of acute diarrhea in young children.
2. Infection is transmitted through contaminated water, and acquired by fecal-oral route.
3. Watery diarrhea is the main clinical presentation. In malnourished children, *Cryptosporidium* frequently causes persistent diarrhea.
4. Nitazoxanide (given for 3 days) is the drug of choice for acute infections.

Chapter 32.7

Ascariasis

Sutapa Ganguly

PHYLUM: NEMATHELMINTHES; CLASS: NEMATODA; GENUS: ASCARIS LINNAEUS; SPECIES: ASCARIS LUMBRICOIDES

Ascaris lumbricoides is the giant roundworm of the humans, responsible for ascariasis in humans. It has a worldwide distribution, being more prevalent in tropical countries such as India, China and South-East Asia. About 25% of the population in these areas is found to be infested with *A. lumbricoides*. The annual global mortality is as high as 20,000, mainly due to intestinal complications and morbidity is 10,00,000 cases mainly due to malnutrition and pulmonary complication. Ascariasis occurs in persons with unhygienic habits.

MORPHOLOGY

The Worm

The adult worm has resemblance to earthworm and is light brown or pink in color when fresh from intestine, but it gradually changes to white. Males are 2–4 mm in diameter and 15–31 cm long. The tail end of the male is curved ventrally in the form of a hook having a conical tip. Females are 3–6 mm in diameter and 20–49 cm long. The worm tapers at both ends, the anterior end being thinner than posterior. The egg-laying capacity of the female *Ascaris* is enormous liberating about 200,000 eggs daily. The digestive and reproductive system floats inside the body cavity containing an irritating fluid. The irritant action is due to the presence of a substance *ascaron* which is protease in nature. The allergic manifestation seen in the infected individuals is due to this ascaron. The adult worm lives in the jejunum and maintains its position against intestinal peristalsis by its muscle tone. It can live in the human host for 12–18 months.

Egg

The eggs liberated by a fertilized female pass out with feces of the human host. The *fertilized egg* is round or oval, 60–70 µm in

length and 40–50 µm in breadth, and golden brown due to bile staining (**Fig. 1A**). It is surrounded by a thick smooth translucent albuminous shell thrown into mammillations. Inside is a large conspicuous unsegmented ovum. There is a clear crescentic area at each pole. It floats in saturated solution of common salt. The female even if not fertilized, is capable of liberating eggs. The *unfertilized eggs* are narrower, longer and more elliptical; they are brownish, have a thinner shell with an atrophied egg inside (**Fig. 1B**). They do not float in salt solution, being heaviest of all helminthic eggs. Both fertilized and unfertilized eggs may be present in the stool. Presence of only unfertilized eggs signifies that the host is harboring female *Ascaris* or mating between males and females has not occurred.

LIFE CYCLE

The worm passes its life cycle in one host and no intermediate host is required. Continuance of the species is maintained by transfer from one individual to another. Man is the only known definitive host of *A. lumbricoides*. The unsegmented, fertilized ovum passed in the stool takes 10–40 days in the soil, depending on the atmospheric temperature and humidity to develop into the mature and infective state. Infections in humans occur when this fertilized egg containing the rhabditiform larva is ingested with food, drink or raw vegetables. Embryonated eggs pass down into the duodenum where the digestive juices weaken the egg shell and stimulate the enclosed larvae into activity. It penetrates the duodenum and enters the blood stream. From there it is carried to the liver and heart, enters the pulmonary circulation to break free into the alveoli, where it grows and moults twice. In 3 weeks the larvae pass from the respiratory system to be coughed and swallowed and thus returned to the small intestine where they moult once and mature into adult male and female worms in 6–10 weeks. The gravid females begin to discharge eggs into the stool about 2 months from the time of infection. The cycle is again repeated (**Fig. 2**).

CLINICAL FEATURES

The adult worm inhabits the upper part of small intestine, thus symptoms are mainly gastrointestinal.

Nutritional Deprivation

The parasite consumes huge amount of calories as they have to thrive against the peristaltic movement of the jejunum. They imbibe the

Figures 1A and B This micrograph reveals (A) fertilized egg of the round worm *Ascaris lumbricoides*; 400x. Fertilized eggs are rounded, have a thick shell; (B) unfertilized egg; it is elongated and larger, thinner shelled, covered by a more visible mammillated layer, sometimes covered by protuberances

Figure 2 Life cycle of *Ascaris*

nutrition from the host who may suffer from protein energy malnutrition in case of heavy infestation. *Ascaris* infection is frequently associated with symptoms and signs of vitamin A deficiency.

Mechanical Effects

Heavy *A. lumbricoides* infestations may cause acute intestinal obstruction due to a ball of worms. It may also result in intussusception. The adult worm may penetrate through the ulcers of the alimentary tract. Children may present with vomiting, abdominal distension and cramps.

Ectopic Ascariases

The worms frequently migrate and may enter the stomach and may be vomited out or may pass up through the esophagus at night, coming out through the nose and mouth. During migration it may enter the glottis, causing laryngospasm and death due to suffocation. Wandering *Ascaris* may enter the lumen of appendix causing appendicitis. Obstructive jaundice and hemorrhagic pancreatitis may occur when the worm enters the biliary passage and/or the pancreatic duct. At times it may penetrate high up in the liver causing liver abscesses.

Allergic Symptoms

Larvae migrating through the tissues may cause allergic symptoms, fever, urticaria and granulomatous disease. It may present as Loeffler syndrome, characterized by fever, cough, dyspnea, pulmonary infiltrates and blood eosinophilia. Larvae may be observed in sputum.

LABORATORY DIAGNOSIS

Direct Evidence

The adult worms may pass out spontaneously with stool or per anum in between the stool (**Fig. 3**). They may be vomited out or pass through the nares. Administration of anthelmintic may lead to expulsion of worms and its detection. Direct microscopic examination of the saline emulsion of stool reveals fertilized and unfertilized eggs. Concentration by floatation method may increase the probability of detections of eggs in the stool. Barium imaging may detect adult worms which ingest the barium within 4 to 6 hours (string like shadows). Ultrasound can detect worms in pancreaticobiliary ducts.

Indirect Evidence

Eosinophilia is present during early stages of invasion. If present in the later stages, suggest associated strongyloidiasis or toxocariasis infection.

Figure 3 A mass of *Ascaris lumbricoides* worms, passed by a child in Kenya, Africa

Source: James Gathany; Public Health Image Library (PHIL), CDC, USA.

TREATMENT

Anthelmintic drugs should be given to the child as well as family members. Albendazole (single dose 400 mg in children aged 2 years and above; and 200 mg in younger children) is the drug of choice. Alternative drugs include pyrantel pamoate (single dose 10 mg/kg to maximum one gram), mebendazole (100 mg twice daily for three days), nitazoxanide, and ivermectin (150–200 mcg/kg single dose).

PREVENTION

Prevention of ascariasis requires hygienic habits and effective fecal treatment systems. This is particularly true for ascariasis as eggs are difficult to kill (they commonly survive 1–3 years). The eggs may get onto vegetables when improperly processed human feces from infected persons are used as fertilizers for food crops. Thus, fruit and vegetables should be washed thoroughly before consumption. Bleach does not easily kill *Ascaris* eggs but removes the sticky film which allows the eggs to be rinsed away.

IN A NUTSHELL

1. *Ascaris lumbricoides* is the giant roundworm of the humans, responsible for ascariasis in humans. It has a worldwide distribution.
2. The adult worm inhabits the upper part of small intestine, thus symptoms are mainly gastrointestinal.
3. Albendazole is the drug of choice. Alternative drugs include pyrantel pamoate, mebendazole, nitazoxanide, and ivermectin.

Chapter 32.8

Hookworm Infestation

Maitreyi Basu, Sutapa Ganguly

PHYLUM: NEMATODA;

FAMILY: ANCYLOSTOMATIDAE;

GENUS: NECATOR/ANCYLOSTOMA;

SPECIES; N. AMERICANUS, A. DUODENALE

Hookworm infestation is an important cause of iron deficiency anemia in the developing countries. Hookworm, a parasitic nematode, lives in the intestine of human host. Two species of hookworms usually infest the humans, namely *Ancylostoma duodenale* and *Necator americanus*. While *A. duodenale* predominates in the Middle East, India and North Africa Western Australia, *N. americanus* infests people in Americas, Sub Saharan Africa, South East Asia, Southern China and Indonesia. Other species of hookworm are zoonotic and include *A. celyanicum*, *A. caninum* and *A. braziliense*. Dog hookworm *A. caninum* can cause eosinophilic enteritis syndrome in humans. *A. braziliense*, a parasite in dogs and cats causes cutaneous larva migrans in humans by its larval stage.

EPIDEMIOLOGY

Hookworm affects more than 500 million people globally. Soil, moisture and warmth are necessary for the parasite to thrive and hence, it is prevalent in rural areas with poor sanitary conditions. Hookworm infestation is associated with economic

underdevelopment and poverty. High rates of infection are seen among agricultural workers and tea garden laborers. People of both sex and all ages are susceptible. *A. duodenale*, also called *Old world hookworm* can withstand harsher climatic conditions. Among Asian countries, it predominates in Northern India, mainly Punjab and Uttar Pradesh, also Sri Lanka and Northern China. *N. americanus*, though called American or *New world hookworm*, has spread to Asian countries and is common in parts of India other than Punjab and UP, Sri Lanka, Southern China and South East Asia.

LIFE CYCLE

Man is the definitive host of hookworm and harbor the adult worms. Multiplication of the worm does not occur inside man. No intermediate host is required for the spread of infection. The eggs containing segmented ova passes through human feces to soil. In 8–10 days, each egg first develops into a rhabditiform larva, 250 µm long, which moults twice to form the infective filariform larva, measuring 500–600 µm in length. The infective larval stage of hookworm remains in a developmentally arrested state in warm and moist soil. Human infection occurs as *A. duodenale* and *N. americanus* larva penetrate skin when man walks barefoot over feces contaminated soil. In gardeners and miners, the skin of the hands may be the portal of entry. *A. duodenale* larva can also infect humans when ingested. Following entry in man, the larva in subcutaneous tissues undergoes extraintestinal migration. They enter into the lymphatics or small venules to reach right heart. From pulmonary circulation, they break into alveoli, migrate upwards through air passages to pharynx and swallowed. Orally ingested larva may develop in intestine. The larva travels the GI tract and settles in small intestine where they develop into adult worms after moulting twice (**Fig. 1**).

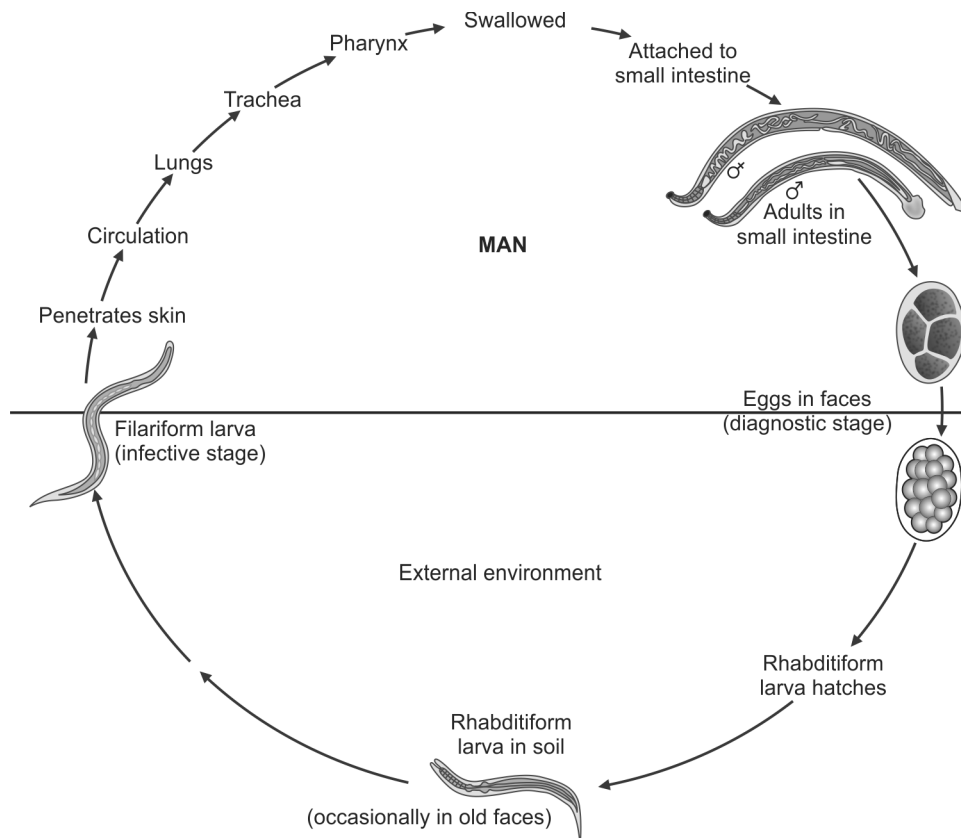

Figure 1 Life cycle of hookworms: *Ancylostoma duodenale* and *Necator americanus*
Source: Public Health Image Library (PHIL), CDC, USA.

The male and female adult worms measure 5–13 mm in length. The buccal capsules of adult *N. americanus* have cutting plates, whereas that of *A. duodenale* has teeth to secure intestinal attachment. The extraintestinal migration and development into adult worms may take 2 months, though *A. duodenale* larva may remain developmentally arrested inside human body for many months. Mature worms can lay eggs up to 10,000–30,000/day. In the intestine, the eggs are laid in an unsegmented stage. During passage through intestine segmentation proceeds up to 4-celled stage (**Fig. 2**). The eggs when passed out in feces are not infective to man.

Translactational transmission of *A. duodenale* larva has been described. The larva may not undergo passage through lungs, remain dormant in muscles and after childbirth reach mammary gland through circulation and infect infants through mother's milk.

PATHOGENESIS

The main consequence of hookworm infestation is iron deficiency anemia due to intestinal blood loss. Heaviest parasite load occurs in children. The adult hookworms attach themselves to the mucosa and submucosa of small intestine with their teeth or cutting plates and remain there with negative suction pressure in the buccal capsules. The worm secretes anti-inflammatory substance to minimize host inflammation at the site of attachment. Capillaries in lamina propria rupture, the worm ingest blood, which is anticoagulated and lysed to release hemoglobin that is digested. Anemia is caused by withdrawal of blood by the parasites and chronic hemorrhage from the puncture sites. *A. duodenale* can draw 0.2 mL blood/day, while *N. americanus* draws 0.03 mL blood/day. It is estimated that loss of hemoglobin for each 12 worms is about 1%. This iron loss cannot be compensated in nutritional deficient individuals. Also, hypoalbuminemia may develop leading to anasarca.

CLINICAL FEATURES

There are no specific signs and symptoms of hookworm infection. Dyspeptic troubles and epigastric discomfort may occur. Symptoms are related to the complications of heavy infections causing iron/protein deficiency. Iron deficient anemia and protein malnutrition occur. Iron deficiency can lead to abnormal appetite showing a perverted taste for things like mud, lime (pica). Prolonged iron deficiency cause physical growth retardation and intellectual defects. Early intestinal infection is associated with eosinophilia. Children with chronic hookworm infection acquire a yellow-green pallor called chlorosis. During migration of *A. duodenale* and *N.*

americanus larva through lungs, laryngotracheobronchitis and pharyngitis can occur giving rise to cough. Eosinophilic enteritis by *A. caninum* cause epigastric pain that increases with food intake and radiate outward. It may simulate appendicitis. An infantile form of ancylostomiasis has been described. There is severe anemia, diarrhea, and melena that may be life-threatening.

Skin Lesions

Ankylostoma dermatitis or ground itch occurs at the site of entry of larva in the skin. There is vesiculation and local edema at the site of entry of larva. It is more common with *Necator* than *Ancylostoma* and persists for 1–2 weeks. This precedes ancylostomiasis by 2–4 months. Creeping eruption or cutaneous larva migrans is a condition when the filariform larva migrates through the skin for months to 2 years and produces a reddish itchy papule along the path of migration. They migrate forming a serpiginous tunnel with roof being formed by stratum granulosum and floor by the corium. This manifest more with *A. braziliense* and *A. caninum* infection, though rarely reported with *N. americanus* larva.

DIFFERENTIAL DIAGNOSIS

Hookworm anemia should be differentiated from other causes of anemia, e.g., nutritional anemia, other causes of iron deficiency anemia and chronic gastrointestinal blood loss especially ulcerative disorders, and diverticulum. Creeping eruption in skin can also occur due to migrating *Strongyloides* larva (larva currens). Complications of tissue migration happen more frequently with roundworm giving rise to similar symptoms. However, intestinal obstruction caused by roundworm is not observed with hookworm infection.

DIAGNOSIS

Macroscopic examination of stool may show adult worms. Microscopic examination of stool helps more in identifying characteristic hookworm eggs. The eggs in stool are colorless, float-in saturated solution of common salt and contain a segmented ovum with four blastomeres. Quantitative methods are available like egg counting in stool to detect heavy worm burden. However, *A. duodenale* and *N. americanus* eggs are indistinguishable. Species can be identified by egg hatching and examination of third stage larva or by examination of mature adult worms. In eosinophilic enteritis caused by *A. caninum*, eggs are not detected in stool. Colonoscopy is done to document intestinal ulcerations; blood shows eosinophilia.

Indirect Evidence

Blood examination reveal microcytic hypochromic anemia; at times dimorphic anemia can occur. Eosinophilia is associated with early enteritis. Stool examination for occult blood is positive. Charcot-Leyden crystals are often found in stool.

MANAGEMENT

Specific treatment consists of deworming with anthelmintic drugs. Albendazole 400 mg per orally in single dose achieves high cure rates. *N. americanus* hookworms may require additional doses for eradication. Albendazole is effective against intestinal stage and also when the worm is migrating under the skin. Mebendazole 100 mg twice daily for 3 days is also effective. Mebendazole can be used in *A. caninum* enteritis. Benzimidazoles (albendazole, mebendazole) are not recommended for treatment of pregnant women in the first trimester due to their potential embryotoxic and teratogenic effect. WHO currently recommends benzimidazole drugs for more than 1 year age. In children 1–2 years of age, 200 mg of albendazole is enough to avoid toxicity. Pyrantel palmoate 11 mg/kg once daily for 3 days is a good alternative. Supportive management includes oral iron replacement. Correction of other protein nutrient deficiencies should be done as needed.

Figure 2 This embryonated egg is indistinguishable between the *Ancylostoma duodenale* or *Necator americanus* hookworm. Note the thin shell, oval or ellipsoidal shape

Source: Public Health Image Library (PHIL), CDC, USA.

PREVENTION

Prevention of hookworm infestation requires good sanitation measures and personal hygiene. Avoidance of walking barefoot over soil and use of night soil as fertilizer may minimize infection. Deworming of pet dogs is also important in this context.

IN A NUTSHELL

1. Hookworm lives in the intestine of human host. Two species of hookworms usually infest the humans, namely *Ancylostoma duodenale* and *Necator americanus*.
2. Hookworm infestation is an important cause of iron deficiency anemia in the developing countries.
3. It also cause creeping eruption or cutaneous larva migrans where the filariform larva migrates through the skin for months to 2 years and produces a reddish itchy papule along the path of migration.
4. Albendazole achieves high cure rates.

Chapter 32.9

Trichuriasis

Sutapa Ganguly

PHYLUM: NEMATODA;**FAMILY: TRICHURIDAE;****GENUS: TRICHURIS;****SPECIES: TRICHURIS TRICHIURA**

Trichuris trichiura, commonly known as the whipworm, resides in the cecum, ascending colon, and appendix. It is distributed worldwide with an estimated 1 billion infections. It is common in warm moist conditions, especially in Asia and to a lesser degree in Africa and South America.

MORPHOLOGY**Adult Worm**

The worm resembles a whip, the anterior three fifth is very thin and hair like and consists of a long esophagus. The thicker posterior portion contains intestine and sex organs. They attach to the host through their slender anterior end and feed on tissue secretions instead of blood. Females are larger than the males, approximately 30–45 mm. The posterior end of females is bluntly round compared to their male counterparts with a coded posterior end. The adult worm may live in the intestine for many years.

Eggs

Trichuris eggs are barrel shaped, brown (bile stained), about 50 X 25 µm. It has a double shell, the outer shell being bile stained. The eggs contain unsegmented ovum when they leave the human host. They float in saturated solution of common salt. The eggs when freshly passed are not infective to man.

LIFE CYCLE

No intermediate host is required. The worm passes the life cycle in one host, man. A change of host is necessary for the continuation of the species. The eggs come out of the human host with feces and the development proceeds in the damp earth or in water. In tropics the rhabditiform larva develops within the eggs in the course of 3–4 weeks. In temperate climates the larva takes a long time (6–12 months) to develop. The embryonated eggs are infective to man. Man is infected when the embryonated eggs are swallowed with food and water. The egg-shell is dissolved by the digestive juices and the larva emerges through one of the poles of the eggs. The liberated larvae pass down into the cecum, their site of localization. They grow directly into the adult worm and embed their anterior parts in the mucosa of the intestine. The worms become sensually mature within a month and the gravid female begins to lay eggs. The female *T. trichiura* lays 2,000–10,000 single celled eggs per day. The cycle is then repeated (Fig. 1).

CLINICAL FEATURES

Incubation period is 60 days. Infection is asymptomatic in most cases. In heavy infections the patient often complains of abdominal pain, mucous diarrhea often with blood streaked stool and loss of weight. Worms inhabiting the vermiform appendix may give rise to symptoms of acute appendicitis. Prolapse of rectum has occasionally been observed in massive trichuriasis.

MANAGEMENT AND CONTROL**Laboratory Diagnosis**

Microscopic examination of a saline emulsion of stool will reveal characteristic barrel shaped eggs (Fig. 2). Adult worms may occasionally be present in the stool. The degree of infection can be determined by the egg count.

Figure 1 Life cycle of *Trichuris trichiura*, the causal agent of Trichuriasis
 Source: Public Health Image Library (PHIL), CDC, USA.

Figure 2 Egg from the “human whipworm”, *Trichuris trichiura*
 Source: CDC/BG Partin. Public Health Image Library (PHIL), CDC, USA.

Treatment

Thiabendazole or mebendazole (100 mg twice daily for 3 days) may be used in the treatment of trichuriasis. Albendazole (400 mg daily for 3 consecutive days) is also effective. Ivermectin 200 µg/kg is also used in combination with albendazole (400 mg).

Prophylaxis

Proper disposal of stool, hand washing, prevention of consumption of uncooked vegetables and fruits grown in native gardens help to prevent trichuriasis.

IN A NUTSHELL

1. *Trichuris trichiura* commonly known as the whipworm, resides in the cecum, ascending colon, and appendix.
2. Infection is asymptomatic in most cases. In heavy infections the patient often complains of abdominal pain, mucous diarrhea often with blood streaked stool and loss of weight.
3. Thiabendazole, mebendazole, or albendazole may be used for the treatment of trichuriasis.

Chapter 32.10

Enterobiasis

Dhrubojoyoti Mridha, Sutapa Ganguly

PHYLUM: NEMATODA;
FAMILY: OXYURIDAE;
SPECIES: *E. VERMICULARIS*

Enterobius vermicularis, also known as pinworm or threadworm is a small nematode (1 cm) that mainly presents with perianal itching. High prevalence of infection is reported from South Asia (39% in Thailand) and India (61%). Prevalence of infection is highest in children 5–14 years of age.

LIFE CYCLE

No intermediate host is required. Each of the eggs, newly laid in perianal skin, containing larva completes its development in 24–36 hour in the presence of oxygen. Infection occurs with ingestion of these eggs (**Fig. 1**). The egg shells are dissolved by the digestive juices and larvae escape in the small intestine where they develop into adolescent worm. After the worm become sexually mature male fertilizes the female and dies. The gravid female then migrates from the small intestine down to the cecum and colon (and also the vermiform appendix) (**Fig. 2**) and resides there until eggs develop. The female then wanders down the rectum and comes out of the anal opening

Figure 2 Section of appendiceal tissue with presence of pinworms, *Enterobius vermicularis*

Source: CDC/Dr George R Heal; Public Health Image Library (PHIL), CDC, USA.

during the night to deposit the eggs in perianal skin. The whole cycle is completed in 2–8 week time. Persons handling the night cloths and bed linens of infected persons often contract the infection.

Both male and female are white in color. Adult male measures 2–4 mm in length and 0.1–0.2 mm across its girth. Posterior third

Figure 1 Life cycle of *Enterobius*

of the body is curved and sharply truncated. It is rarely seen except after a purge because it usually dies after fertilizing the female. Adult female measures 8–12 mm in length and 0.3–0.5 mm across its thickest part. The number of eggs in a gravid female pinworm range from about 11,000 to 16,000.

TRANSMISSION

Pinworms spread through human-to-human transmission, by ingesting (i.e., swallowing) infectious pinworm eggs. Eggs do not tolerate heat well, but can remain infectious in moist and low temperatures for up to 3 weeks. As freshly laid eggs are sticky, they are easily transmitted from perianal region to fingernails, hands, night-clothing, bed linen, toys, bathroom fixtures, food, and furs of household pets, water and other objects. Shaking out bed clothes and linen frequently makes the tiny eggs airborne which when gets inhaled and be swallowed later initiates infection. Some of the hatched pinworm larvae enter the gastrointestinal tract of the original host by upward migration from perianal region which is known as *retroinfection*; it leads to a heavy parasitic load and ensures that the pinworm infestation continues.

Eggs get deposited in fingertip when children put their finger in perianal area for scratching which, when kept inside mouth initiates life cycle of worm (*autoinfection*). As children have inherent tendency to put their finger inside mouth and other members of the family are often infected, persistence of infection and reinfection after treatment is very common in children.

CLINICAL FEATURES

Most common symptom is perianal pruritus. Other manifestations include cellulitis, granuloma or abscess in the perianal area resulting from scratching due to intense itching. Girls may develop vaginitis and urinary tract infection. Complications include chronic salpingitis, hepatitis, pelvic inflammatory disease, and peritonitis from aberrant migration of worms. Eosinophilic ileocolitis is rare.

DIAGNOSIS

Finding the female worm or the eggs confirms the diagnosis of pinworms. At night, the adult worms can sometimes be seen directly around the anal area or in pajamas. The worm (one-quarter to one-half inch long) should be removed and preserved in 75% ethyl alcohol until microscopic examination. If adult worms are not visible, conduct a tape test in the morning. Apply a piece of transparent adhesive tape against the folds of skin around the anus to pick up any eggs or worms. Seal in a plastic bag and send for microscopic examination. Repeated examination increases the chance of detecting ova which is plano-convex, and not bile stained, surrounded by a transparent shell, contains a tadpole like larva and floats in saturated solution of common salt.

Pinworms are rarely spotted in stool samples. Because bathing or a bowel movement can remove the eggs, the tape test should be done as soon as the person wakes up in the morning. Enterobiasis

need to be differentiated from Crohn disease, hidradenitis suppurativa, proctitis, anusitis, and ulcerative colitis.

TREATMENT AND PREVENTION

Pinworm infection can be cured. Anthelmintic drug should be given to infected child as well as family members. Drug of choice is single oral dose of albendazole (400 mg), mebendazole (200 mg) or pyrantel pamoate (11 mg/kg); dose to be repeated after 14 days. It is important to take appropriate care and maintain hygiene to prevent autoinfection. Morning bath and frequent change of underclothing should be encouraged. Washing of bed cloth, bed sheet twice a week decreases risk of autoinfection. Keep fingernails short and clean. Discourage nail biting. Clean toilet seats daily. Wash hand before meal and after using toilet.

IN A NUTSHELL

1. Enterobiasis is caused by a pinworm that mainly affects children 5–15 years.
2. Infection is acquired through ingestion of eggs. Autoinfection causes worm to inhabit the same host indefinitely. Retroinfection is also common and clinically significant.
3. Most common symptom is perianal pruritus. Pinworm infection should be kept in mind in a girl with vaginal pruritus or urinary tract infection.
4. Stool examination is not helpful for diagnosis. Repeated microscopy of adhesive tapes that has been applied to the perianal area early in the morning before bath, increases chance of detection of pinworm ova.
5. As none of the anthelmintics is effective against eggs, two doses of albendazole/mebendazole/pyrantel pamoate are advised, 14 days apart.

Chapter 32.11

Strongyloidiasis

Ravi Ambey, Tripty Naik

Strongyloidiasis is a chronic parasitic infection of humans caused by soil transmitted helminths, *Strongyloides stercoralis*. In malnourished children, strongyloidiasis remains an important cause of chronic diarrhea, cachexia and failure to thrive. Without appropriate therapy, the infection does not resolve and may persist for life. It has the potential for severe and life-threatening infection in cases of immunodeficiency (hematologic malignancies and immunosuppression) with 60–90% mortality rate. The infection is most common in tropical and subtropical countries with nearly 30–100 million people being infected worldwide. Precise data are unknown as the infection is mostly asymptomatic and the diagnostic methods lack sensitivity.

ETIOLOGY

Strongyloidiasis is caused by nematode or roundworm of genus *Strongyloides*. Of the 40 species, *S. stercoralis* mainly causes disease in human. The free-living larvae enter the body through exposed skin such as barefoot, contact with human waste or sewage. Like other soil-transmitted helminthiasis the risk of infection is associated with hygiene, making children especially vulnerable

to infection. There have been rare cases of person-to-person transmission in organ transplantation.

PATHOGENESIS

The life cycle of *S. stercoralis* (Fig. 1) has two stages: (i) a free-living life cycle (rhabditiform larvae) and (ii) a parasitic life cycle (filariform infective larvae) with three developmental forms: (i) adult, (ii) rhabditiform larva and (iii) filariform larva. The infective filariform larva presents in soil enters the body through skin, enters blood stream and reaches lungs. It traverses the tracheobronchial tree and is swallowed in gastrointestinal tract. In intestine, it develops into adult female and passes egg. The eggs instead of passing in feces hatch in intestine as rhabditiform larvae. Larvae develop into infective filariform larvae which reinfect the host by invading intestine or the skin of perineum, buttocks and thighs. This is known as *autoinfection* and is unique for *Strongyloides* infection. Alternatively, the rhabditiform larvae hatched from the eggs pass with feces into the soil. Symptoms result when larva migrates through various tissues of body. Impaired host defense and repeated autoinfection cause hyperinfection syndrome and larvae to disseminate throughout body. The risk factors for hyperinfection or disseminated disease are summarized in **Box 1**. Human T-cell lymphotropic virus type 1 (HTLV-1) infection has a bidirectional relationship with *Strongyloides*; coinfection with *Strongyloides* shortens the preleukemic phase of HTLV-1 infection; the *Strongyloides* antigen accelerates leukemogenesis, and treatment of the *Strongyloides* infection may actually decrease HTLV-1 viral load.

Figure 1 Life cycle of *Strongyloides stercoralis*

Source: Public Health Image Library (PHIL), CDC, USA (Content provider: CDC/Alexander J da Silva, Ph D/Melanie Moser, 2002)

BOX 1 Risk factors for hyperinfection or disseminated disease with *Strongyloides*

- Alcoholism
- Chronic renal failure and end-stage renal disease (ESRD)
- Diabetes mellitus
- HIV/AIDS
- Human T-cell lymphotropic virus type 1 (HTLV-1) infection
- Hypogammaglobulinemia
- Malignancy or neoplasm, particularly hematologic malignancies (lymphoma, leukemia)
- Malnutrition
- On treatment with corticosteroids or other immunosuppressives
- Solid organ and bone marrow transplant

CLINICAL FEATURES

Most infections with strongyloidiasis are asymptomatic. Acute infection may cause rash, petechiae and itch at the site of entry of parasite. Symptoms, if present, are mostly nonspecific respiratory and gastrointestinal in the form of cough, tracheal irritation, wheeze, abdominal pain, abdominal fullness, diarrhea and constipation. Many times infection may remain undiagnosed for life. *Chronic infection* may cause growth failure, malabsorption, protein-losing enteropathy or may mimic asthma. Cutaneous symptoms include chronic urticaria and the pathognomonic larva currens—a recurrent serpiginous maculopapular or urticarial rash along the buttocks, perineum, and thighs due to repeated autoinfection. It has been described as advancing as rapidly as 10 cm/hour.

Strongyloides causes hyperinfection or disseminated disease in immunocompromised because of autoinfection and its unique ability to multiply indefinitely within intestinal wall of the host. Hyperinfection syndrome implies signs and symptoms due to increased larval migration. Increased number of larvae is detected in feces or sputum. Disseminated infection occurs when larvae migrate beyond organs of autoinfective cycle (lungs and gut).

COMPLICATIONS

Hyperinfection is characterized by exaggeration of the symptoms found in immunocompetent host and is limited to gastrointestinal and respiratory manifestations. Disseminated strongyloidiasis involves almost all systems of the body—cutaneous, gastrointestinal, respiratory and central nervous system. Frank bacteremia and septicemia (mainly Gram-negative sepsis) can occur due to introduction of gut flora through disrupted mucosal barrier into blood stream. Unawareness of the condition, nonspecific manifestations and low sensitivity laboratory tests cause significant delay in diagnosis and a mortality rate approaching 90%.

DIFFERENTIAL DIAGNOSIS

- *Recurrent asthma*: Nonresponse to bronchodilators and steroids and worsening course may suggest *Strongyloides* infection.
- *Acute respiratory distress syndrome*: Sputum examination leads to diagnosis.
- *Other intestinal infections* (amebiasis, bacterial colitis, shigellosis): Strongyloidiasis is diagnosed by demonstration of organism in stool specimen.
- *Inflammatory bowel disease*, especially ulcerative colitis: History of steroid therapy, chronic colitis refractory to conventional immune-modifying management and endoscopic finding of distal attenuation of the colitis are helpful clues to the diagnosis of strongyloidiasis.

- *Pneumonia* in immunocompromised (*Pneumocystis*, *Cryptococcus*, *Mycobacterium*): Strongyloidiasis diagnosed by presence of larvae in sputum.
- *Loeffler pneumonia* (eosinophilic infiltration of lungs): Strongyloidiasis is one of the causes of the disease.
- Peritonitis and abdominal sepsis.

DIAGNOSIS

Mild peripheral eosinophilia and elevated IgE levels are present in 75% of chronic infections. Multiple stool examinations to detect larva in direct stool smear examination is the gold standard for diagnosis of strongyloidiasis. Chronic strongyloidiasis has low larval load and intermittent larval excretion in stool, therefore a single stool examination fails to detect 70% cases (sensitivity only 30–50%). Sensitivity increases to almost 100% with examination of seven stool samples. Several fecal concentration techniques are used to increase larval detection rate in feces including direct smear of feces in saline—Lugol iodine stain, Baermann concentration and nutrient agar plate cultures (APC). Hyperinfection is easier to detect due to higher parasite load.

Duodenal fluid aspiration via endoscopy or string test increases detection rate. Larvae can also be detected in sputum, cerebrospinal fluid (CSF), bronchoalveolar lavage (BAL) and intestinal biopsy in case of dissemination. Enzyme-linked immunosorbent assay (ELISA) for IgG antibody to *Strongyloides* is more sensitive (88–95% in various studies) than stool examination. Unfortunately, the test is not easily available and has cross reactivity with other helminth infections (filariasis, ascariasis and schistosomiasis). A significant decrease in antibody titer after 6 months of therapy can be used as a marker of cure. Luciferase immunoprecipitation system (LIPS) has better sensitivity (99%) and specificity (100%) than ELISA and less cross reactivity with other filarial antigens. Various imaging techniques and endoscopy can be used to detect gastrointestinal complications.

MANAGEMENT

Treatment for strongyloidiasis is recommended for all infected persons, whether symptomatic or not, due to the risk of developing hyperinfection syndrome and/or disseminated strongyloidiasis. Treatment of strongyloidiasis as recommended by Centers for Disease Control and Prevention (CDC) is summarized in **Box 2**. Patients hospitalized with strongyloidiasis should be placed on contact precautions. In patients with positive stool examination for *Strongyloides* and persistent symptoms, follow-up stool exams should be performed 2–4 weeks after treatment to confirm clearance of infection. If recrudescence of larvae is observed, retreatment is indicated.

BOX 2 CDC guidelines for treating strongyloidiasis**Acute and Chronic Strongyloidiasis**

Ivermectin, in a single dose, 200 µg/kg orally for 1–2 days. Relative contraindications include persons weighing less than 15 kg and those with confirmed or suspected concomitant *Loa loa* infection.

OR

Albendazole, 400 mg orally twice a day for 7 days. Hypersensitivity to benzimidazole compounds is a relative contraindication. It can be used in children as young as 1-year-old.

Hyperinfection Syndrome or Disseminated Strongyloidiasis

Ivermectin, 200 µg/kg/day orally until stool and/or sputum exams are negative for parasites for 2 weeks. For patients unable to tolerate oral therapy (ileus, obstruction, malabsorption), rectal or subcutaneous route can be used. Stop or reduce immunosuppressive therapy if being administered.

OUTCOME

Strongyloides hyperinfection or dissemination has a mortality rate approaching 90%. This is due to delay in diagnosis because of lack of awareness of the condition, nonspecific disease manifestations, poor detection rate in stool smear, no availability of better diagnostic tests and also due to unavailability of ivermectin in some endemic countries and selection of improper first-line therapy due to lack of standardized treatment guidelines.

PREVENTION

Strongyloidiasis, like other soil transmitted infections, can be prevented by proper hygiene, avoiding barefoot, hand washing and avoiding use of sewage as fertilizer. Severe infection can be prevented by screening for and treating asymptomatic strongyloid infection in HTLV-1 and malignancy patients and prior to starting steroid or immunosuppressive therapy.

IN A NUTSHELL

1. Strongyloidiasis is a potentially fatal disease transmitted due to unhygienic condition.
2. Strongyloid has the unique ability of autoinfection and reinfecting host causing the parasite to remain in the host for decades or even life unnoticed.
3. Infection is mostly asymptomatic in immunocompetent and symptoms if occur are nonspecific.
4. Immunosuppression (malignancies and steroid therapy) and HTLV-1 infection are the most important risk factor for hyperinfection or dissemination with mortality 65–90%.
5. Peripheral eosinophilia is seen in 65% cases of chronic infection but is rare in disseminated disease.
6. Multiple-stool smear for detection of larva is gold standard for diagnosis of strongyloidiasis.
7. Infection, even if asymptomatic, warrants treatment and proper follow-up by fecal smear examination after completion of therapy.
8. Ivermectin is the drug of choice.
9. Screening of patients (especially with peripheral eosinophilia) for strongyloid infection prior to immunosuppressive therapy can prevent fatalities due to disease.
10. Treating physicians need to be aware of the condition to prevent delay in diagnosis.

Chapter 32.12

Trichinosis

Akash Bang, Puja Hingorani

Trichinosis (or trichinellosis) is a parasitic infection caused by the nematode *Trichinella*, most commonly acquired through the consumption of the undercooked meat.

EPIDEMIOLOGY

Trichinosis is distributed all over the world, but most commonly in Asia, Latin America and Central Europe. Cases usually tend to cluster among groups that have consumed meat from a common infected source. Since undercooked meat is the common source of infection in humans, cultural factors and food preferences play an important role in the epidemiology. Cattle and other pure herbivores are not naturally infected, so people preferring beef are not at high-risk unless there is contamination with the pork. Sanitation is another important environmental determinant. Poor disposal of the animal meat, carcasses or dead bodies increase the risk of circulation of *Trichinella* in the peri-urban animals like pigs who become infected after feeding on such infectious source. Also, hunting and eating wild animals increases the risk. Human travel, translocations of animal populations and export of food have further contributed to the reemergence of the disease.

ETIOLOGY

Human trichinosis is caused by the tissue-dwelling nematode, *Trichinella*. *Trichinella spiralis* is the commonest species and is found worldwide in a variety of carnivorous and omnivorous animals. It shows encystment and infects only mammals. There are seven more species of *Trichinella*, some of which do not show encystment and also infect birds and reptiles in addition to mammals.

LIFE CYCLE

Trichinella exists in two types of life cycles: (i) a domestic cycle involving pigs, rodents, horses, etc., and (ii) a sylvatic cycle involving wild animals. Human infection occurs upon ingestion of inadequately cooked infected meat that contains the encysted larvae. Most frequent source is the undercooked pork. On exposure to the gastric acid and pepsin, the cyst walls are digested in the stomach and the larvae are released. They pass into the small intestine and invade the small intestine columnar epithelium at the villi base where they develop into adult worms around 1–2 mm in length. Fertilized female worms start releasing new larvae about 1 week after ingestion and continue for next 3–4 weeks. The life of an adult worm in intestine is around 4 weeks after which they are expelled in feces. The larvae released by the adult females invade the circulation and migrate to the striated muscles. In the striated muscles the larvae burrow into individual muscle fibers, increase up to 10 times in length and undergo encystment (Fig. 1). Encysted larvae can remain viable for years and can infect a new host if ingested.

PATHOGENESIS

In the initial couple of weeks after infection, the gastrointestinal tract gradually shows a mild, partial villus atrophy and an inflammatory infiltrate in the mucosal and submucosal layers.

The larvae released by adult female worms disseminate over the next several weeks. Skeletal muscle fibers may show edema,

Figure 1 *Trichinella spiralis* cysts seen embedded in a muscle tissue specimen
Source: Public Health Image Library (PHIL), CDC, USA.

basophilic degeneration and a coiled encysted worm surrounded by lymphocytic and eosinophilic infiltrate.

CLINICAL FEATURES

The severity of infection depends on the ingested larvae load. The incubation period is usually 1–4 weeks and also depends on ingested larvae load, host immune status and the invasiveness of the species of *Trichinella*. Mild infections can be subclinical without any marked symptoms or signs. Clinically apparent trichinosis usually follows two stages:

1. **Intestinal stage** This stage occurs between 2 days and 7 days after ingestion and correlates with the release of the encysted larvae from the ingested meat in the stomach due to acid-pepsin digestion, their burrowing into the intestinal mucosa and maturation into adult worms. Diarrhea is the commonest complaint. Other clinical features include abdominal pain, nausea and vomiting. Reinfection in patients with previous infection and sensitization may cause a persistent diarrhea lasting for weeks. Extremely high worm load may cause a fulminant enteritis.
2. **Muscle stage** This stage occurs after 1 week after ingestion and correlates with the hematogenous spread of the larvae, their entry into skeletal muscles and the subsequent inflammatory reaction. Clinical features include extreme muscle pain which at times may limit all movements, high fever, muscle swelling, tenderness and weakness. Usually affected areas include calves, forearms, upper arm, neck and shoulder girdle. Subungual splinter hemorrhages (Fig. 2), conjunctival or retinal hemorrhages, periorbital edema and chemosis, vision disturbances, headache and ocular pain may be observed. Less common manifestations are macular, petechial or urticarial rash, cough, dyspnea, dysphagia, and hepatomegaly. Severe infections may lead to death due to myocarditis, encephalitis or pneumonia. As the encystment occurs, clinical manifestations gradually resolve. Encysted larvae can persist for several years before they calcify and die.

Ocular Manifestations of Trichinosis

These need special mention as many times patients may present only because of various ocular manifestations which result from larval invasion into the extraocular and the orbicularis

Figure 2 Trichinosis is manifested by splinter hemorrhages under the finger nails

Source: CDC/Thomas F Sellers/Emory University; Public Health Image Library (PHIL), CDC, USA.

muscles. Most characteristic and notable ocular manifestation is chemosis of the bulbar conjunctiva with slight inflammatory reaction (classically described as *pale lemon jelly appearance*) that is limited usually to the conjunctiva overlying the medial and lateral recti muscles and fading out to the limbus due to the early invasion of the recti muscles by *Trichinella*. Other frequently associated features include lid edema slowly progressing to surrounding areas causing the typical periorbital puffiness, painful eye movements, exophthalmos, pupillary dilation, conjunctivitis, subconjunctival hemorrhages and both superficial and deep retinal hemorrhages.

DIAGNOSIS

Diagnosis is based on clinical features and is confirmed by serology and/or muscle biopsy.

Clinical features of muscle pains, fever and periorbital edema with a history of ingestion of either inadequately cooked meat (especially pork) or a meat source also ingested by other symptomatic individuals should strongly indicate trichinosis.

Laboratory abnormalities appear during the muscle stage. Eosinophilia is the hallmark and in the 2nd–4th week after infection, eosinophils may constitute up to as much as 90% of the leukocyte count. Degree of eosinophilia is not a prognostic indicator. Sudden eosinopenia may develop secondary to inflammation or due to secondary bacterial infection and is considered a poor prognostic sign. Other possible abnormalities include leukocytosis, elevated creatine kinase and lactate dehydrogenase and hypergammaglobulinemia.

Serological tests include enzyme-linked immunosorbent assays (ELISA), indirect immunofluorescence, latex agglutination tests and are generally reliable but not very useful for early diagnosis since antibodies are detectable only after about 3 weeks after the infection. Also, antibody titers do not correlate with the clinical severity and may remain elevated for years after symptoms subside. Autoimmune diseases and other helminthiasis can give a false-positive antibody test.

Muscle biopsy is confirmatory but rarely needed. The biopsy should be taken from the swollen, tender muscle, preferably near the tendinous insertion. The Centers for Disease Control

and Prevention (CDC) diagnostic criteria for trichinosis requires positive serology or muscle biopsy for *Trichinella* with one or more compatible clinical symptoms such as eosinophilia, fever, myalgia and periorbital edema and history of consumption of potentially contaminated meat.

MANAGEMENT

Mild, subclinical or asymptomatic infections are self-limiting and do not need any anthelmintic treatment. Children below 2 years of age also should not be given anthelmintic therapy. Such patients can be managed symptomatically. Symptomatic management includes management of diarrhea, prevention and treatment of dehydration, antiemetics, analgesics and anti-inflammatory agents for fever, muscle pains. Ocular steroid drops and ointments may relieve the chemosis and ocular pain. Severe ocular pain may require retrobulbar injection of triamcinolone.

For intestinal stage, albendazole (400 mg orally twice a day for 8–14 days for all ages above 2 years) or mebendazole (200–400 mg orally thrice a day for 3 days, then 400–500 mg thrice a day for 10 days for all ages above 2 years) should be administered. For muscle stage, there is no consensus for treatment. Systemic corticosteroids (prednisolone 2 mg/kg/day for 10–14 days) may be added to the above anthelmintic therapy in severe infections especially if there are neurological, cardiac, pulmonary, or such systemic symptoms (**Box 1**).

PREVENTION

Health education and public awareness about avoiding consumption of raw or inadequately cooked meat forms the mainstay of the primary prevention. Public health measures that can reduce infection with *Trichinella* include stringent rodent control, prevention of exposure of pigs and other livestock to animal carcasses or to wild animals and certification of meat products.

BOX 1 Summary of trichinosis

Clinical features:

- Intestinal stage (1st week): Diarrhea, abdominal pain, vomiting
- Muscle stage (2nd–4th week and beyond): Fever, myalgia, muscular tenderness and swelling, periorbital edema
- Complications: Encephalitis, pneumonia, myocarditis.

Investigations:

- Complete blood count: Eosinophilia, leukocytosis
- Elevated muscle enzymes: Creatine kinase, lactate dehydrogenase
- Hypergammaglobulinemia
- Serological tests to detect antibodies: ELISA, latex agglutination, immunofluorescence
- Muscle biopsy.

Diagnostic criteria (CDC): (All three criteria required)

- History of ingestion of undercooked meat
- Compatible clinical features (muscle pains, fever, eosinophilia) and
- Positive serology or muscle biopsy.

Treatment:

- Mild/asymptomatic/subclinical infections or age below 2 years: Symptomatic
- Severe infection and age above 2 years: Albendazole 400 mg PO BID for 8–14 days or mebendazole 200–400 mg PO TID for 3 days, then 400–500 mg PO TID for 10 days
- Systemic complications: Add prednisolone 2 mg/kg/day for 10–14 days

IN A NUTSHELL

1. Trichinosis is caused by the nematodes of *Trichinella* genus. Pigs are the most common source of infection and mode of transmission is ingestion of undercooked meat.
2. Severity of infection depends on the ingested larvae load. Mild infections are asymptomatic. Heavy infections present with the intestinal stage in the 1st week of infection and muscle stage in next 3–4 weeks. Complications include encephalitis, pneumonia or myocarditis.
3. Diagnosis requires history of consumption of potentially contaminated meat, one or more compatible features such as eosinophilia, fever, myalgia and periorbital edema and either a positive serology or muscle biopsy. Serology is not useful in the first 2–3 weeks of infection. Eosinophilia develops during the 2nd week of the muscle stage.
4. Most infections are uncomplicated, self-limited, mild and do not require anthelmintics. Severe trichinosis with systemic symptoms should be treated with albendazole or mebendazole.

Chapter 32.13

Filariasis

Ajay Gaur

Filarial worms are arthropod transmitted nematodes or round-worms that dwell in the subcutaneous tissues and the lymphatics. Each goes through a complex life cycle that includes an infective larval stage carried by the insects and an adult worm stage that resides in humans either in the lymph nodes or adjacent lymphatics or in the subcutaneous tissue.

The adult female worm produces *microfilariae*. These offspring either circulate in the blood or migrate through the skin. The microfilariae can be ingested by the appropriate biting arthropod and develop into infective larvae that are capable of initiating the life cycle once more (*Wuchereria bancrofti*), circulate in the blood with defined circadian rhythm or *periodicity* which can be nocturnal (typically the lymphatic filariae). When absent from the peripheral blood, the microfilariae of filarial parasites are found in the deeper visceral capillaries, particularly in the pulmonary capillaries. Adult worms are long-lived, whereas the life spans of microfilariae range from 3 months to 3 years.

EPIDEMIOLOGY

Lymphatic filariasis (LF) is caused by three species, *W. bancrofti*, *Brugia malayi* and *Brugia timori* which together infect an estimated 120 million persons in Africa, southern Asia, the western Pacific Islands, the Atlantic coast of south and central America and the Caribbeans particularly Haiti and the Dominican Republic. Countries with the highest prevalence include India, Indonesia, Papua New Guinea, Nigeria, Ghana, Kenya and Tanzania. Most heavily infested areas in India are the states of Andhra Pradesh, Tamil Nadu, Kerala, Orissa, Bihar and eastern Uttar Pradesh. In India, most of the cases (98%) are accounted for by bancroftian filariasis which is mostly found in Kerala. There is no animal reservoir for *W. bancrofti*.

The various human parasites in this category (Table 1) have certain characteristics in common. They all are spread by vectors and the adults invade and occupy the lymphatics, skin, connective tissue or blood. They produce live embryos called microfilariae that enter bloodstream or skin where they can survive for months or years with further development. The range of disease caused by

these worms is wide; some produce no symptoms whereas others can be responsible for severe clinical disorders.

PATHOPHYSIOLOGY

The primary pathology is compromised lymphatic function. Adult worms induce lymphatic dilatation that results in lymphatic dysfunction, lymphedema and a greater susceptibility to bacterial infection. The consequent inflammation, plus that caused by host responses to dying parasites, damages the delicate lymphatic vessels and compromises lymphatic function further. When such processes occur in lymphatic vessels of the scrotum, hydrocele develops. Live motile worms exhibiting the *filarial dance* sign and nearby dilated lymphatic vessels can be detected by ultrasonography of the scrotum, inguinal lymph node and breast. Microfilaremia often is *asymptomatic*, but frequently associated with immune complex nephritis; more rarely, the microfilariae can be target of immunologic hyper responsiveness and result in a severe *tropical pulmonary eosinophilia* (TPE) syndrome.

It is not clear why the majority of infected individuals remain asymptomatic while others develop acute or chronic manifestations of lymphatic filariasis. Many persons with chronic lymphedema of the extremities have no evidence of active infection (particularly in India), whereas this is not the case in other *W. bancrofti* endemic areas such as Papua New Guinea. Adaptive T-cell responses, genetic susceptibility, worm burden and innate immunity to the *Rickettsia* like endosymbiont *Wolbachia* of filarial parasites have been suggested to contribute to the complex clinical phenotypes of lymphedema and hydrocele, but a single unifying mechanism is not defined.

LIFE CYCLE

Infection is initiated when female mosquitoes release infective 3rd stage larvae into the puncture site of the skin created during blood feeding. These larvae pass rapidly through the dermis and enter local lymphatic vessels where they molt to form 4th stage larvae. Over 6–9 months, the parasites undergo another molt in afferent lymphatic vessels and eventually develop into sexually mature adult male and female worms. Adult worms largely reside in afferent lymphatic vessels of the upper and lower extremities and the lymphatic of the male genitalia, such as those draining the epididymis, testicles and spermatic cord. Other areas of the body may also harbor adult worms such as skin. Fecund female worms release as many as 10,000 1st stage larvae (commonly referred to as microfilariae) per day, which migrate from the lymphatics

Table 1 Characteristics of filarial parasites

Species	Adult	Microfilaria	Geographic distribution	Vector	Periodicity	Location	Size (μm)	Tail	Sheath	
									Presence	Staining properties
<i>Wuchereria bancrofti</i>	Lymphatics	Blood	Tropics worldwide	Mosquitoes	Nocturnal or sub-periodic	Blood, hydrocele fluid	298 by 7.5–10	Pointed tail devoid of nuclei	+	Does not stain
<i>Brugia malayi</i>	Lymphatics	Blood	Southeast Asia	Mosquitoes	Nocturnal or sub-periodic	Blood	270 by 5–6	Nuclei in tail	+	Bright pink with Giemsa
<i>Brugia timori</i>	Lymphatics	Blood	Indonesia	Mosquitoes	Nocturnal	Blood	300 by 5–6	Nuclei in tail	+	Tends not to stain
<i>Loa loa</i>	Connective tissue	Blood	West and Central Africa	Deer fly (chrysops)	Diurnal	Blood	Up to 300	Irregularly arrange red nuclei extend to end of tail	+	Does not stain

and enter the bloodstream. Microfilariae in peripheral blood are ingested by mosquitoes and undergo development to infective 3rd stage larvae after completing two molts in the mosquito over a period of 14 days. Adult worms are larger than microfilariae ($100 \times 0.25 \text{ mm}$ and $150 \times 7 \mu\text{m}$ respectively) and have reproductive life span of 5–7 years. A characteristic feature of LF in most endemic areas is the nocturnal periodicity of microfilaremia. Peak levels of parasites appear in peripheral blood at night when the mosquito vectors are seeking a blood meal. During the day, microfilariae are sequestered in deep vascular beds and may not be detectable in peripheral blood (**Fig. 1**).

CLINICAL FEATURES

Lymphatic filariasis is associated with a variety of clinical manifestations. The four most common presentations are asymptomatic (or subclinical) microfilariaemia, lymphedema, hydrocele and acute attacks. Less frequently LF can present with chyluria or tropical eosinophilia. The range of clinical disease varies across geographic locations and according to the species of nematode causing the infection. The early signs and symptoms include episodic fever, lymphangitis of an extremity, lymphadenitis (especially the inguinal and axillary areas), headache and myalgia that last a few days to several weeks. These symptoms are caused by an acute inflammatory response triggered by death of adult worms.

Most infected persons are asymptomatic, filarial lymphadenopathy is seen commonly in infected children, before puberty.

Adult worms can be detected by ultrasonography of the inguinal and axillary lymph nodes and vessels. In boys after puberty, the adult worms tend to live in the intrascrotal lymphatic vessels. Ultrasonography of lymphatic vessels may reveal motile adult worms termed the *filarial dance sign*. Even in asymptomatic people, the presence of living adult worms leads to lymphatic dilatation and abnormal lymph flow which can be demonstrated by lymphoscintigraphy. These changes predispose the person to lymphedema. Lymphatic vessel dilatation and lymph node enlargement and fibrosis also can be visualized when lymph nodes are examined histopathologically. Microscopic hematuria and proteinuria also are found.

A separate and clinically distinct syndrome, which for years was confused with filarial lymphangitis, is acute dermatolymphangioadenitis caused by bacterial infection of the small collecting lymphatic vessels in areas of lymphatic dysfunction. Unlike true filarial lymphangitis, this syndrome develops in a reticular rather than a linear pattern and is more commonly associated with severe pain fever and chills.

Lymphedema occurs in the legs, scrotum, penis and arms. In the legs and arms, it is usually unilateral. The most important factor involved in progression of filarial lymphedema to elephantiasis is repeated episodes of acute dermatolymphangioadenitis, originating from breaks in the epidermis, which contribute to further lymph stasis, secondary bacterial infection and fibrosis.

Figure 1 Life cycle of *Wuchereria bancrofti*

Source: CDC/Alexander J da Silva/Melanie Moser. Public Health Image Library (PHIL), CDC, USA.

Tropical Pulmonary Eosinophilia

Tropical pulmonary eosinophilia is a distinct syndrome that develops in some individuals infected with LF species. This syndrome affects males more often than females, most commonly during the third decade of life. The main features include a history of residence in regions where filariae are endemic, paroxysmal cough and wheezing that are usually nocturnal, weight loss, low-grade fever and adenopathy. Patients are rarely found to have microfilariae in the blood. The X-ray findings may occasionally be normal, but increased bronchovascular markings discrete opacities in the middle and basal regions of the lung or diffuse miliary lesions are usually present. Recurrent episodes may result in interstitial fibrosis and chronic respiratory insufficiency in untreated individuals. Tests of pulmonary function show restrictive abnormalities in most cases and obstructive defects in one-half of the cases. Total serum immunoglobulin E (IgE) levels (10,000–100,000 ng/mL), peripheral blood eosinophilia ($>2,000$ cells/mm³) and antifilarial antibody titers are characteristically elevated. TPE is considered to be a form of occult filariasis, in which rapid clearance of the microfilariae occur, presumably on the basis of host immunologic hyper responsiveness to the parasite. Although there is no single clinical or laboratory criterion that aids in distinguishing TPE from other pulmonary disease; residence in the tropics, the presence of high levels of antifilarial antibodies and a rapid clinical response to diethylcarbamazine (DEC) favor the diagnosis of TPE. The clinical response to DEC (2 mg/kg/dose TID PO for 12–21 days) is the final criterion for diagnosis; the majority of patients improve with this therapy.

DIAGNOSIS

Direct Examination

A definitive diagnosis is made by microscopic detection of microfilaria in the blood or occasionally from other sites such as fluid aspirated from hydrocele. The circulation of microfilariae in peripheral blood is periodic with highest concentrations occurring at night, therefore blood specimens should be collected between 10 pm and 2 am. Microfilariae of the three species are distinguished morphologically. Because infected children are frequently microfilaria negative, other tests may be helpful in making the diagnosis. Long et al. describe an interesting approach to the laboratory diagnosis of filariasis using an acridine orange serves as the basis for this test. On centrifugation, parasites become concentrated in the buffy coat and can be visualized through the clear glass wall of the tube. The acridine orange stains the DNA of the parasites and the morphologic characteristics including the nuclear patterns in the tail sections can be examined by fluorescence microscopy in making a species identification. Because microfilariae may be present in the blood in only small numbers, sensitive procedures such as nuclepore filtration and Knott's concentration are also used routinely to detect infections.

Antigen Detection

Assays for circulating antigens of *W. bancrofti* permit the diagnosis of microfilaremic and cryptic infection. Two tests are commercially available. One is an enzyme-linked immunosorbent assay (ELISA) and other is a rapid format immunochromatographic cartridge. Both assays have sensitivities that range from 96% to 100% and specificities that approach 100%. Both tests can be used on blood drawn any time of day or night, thus avoiding the need for specific bleeding times depending on periodicity of microfilariae.

Nucleic Acid Detection Techniques

The advent of polymerase chain reaction (PCR) assays is proving to be useful not only in establishing a diagnosis, but also for use

in monitoring therapy and in discrimination between past and present infection. PCR based assays that detect as little as one microfilaria per milliliter of blood have been described. PCR can detect parasite DNA and is now the most sensitive technique for definitive diagnosis. For each of the lymphatic dwelling parasites, primers and probes have been identified that are 100% specific and provide sensitivities that are up to ten folds greater than parasite detection by direct examination.

Serologic Tests

Immunologically based diagnosis with measured IgG or IgG4 responses against crude extracts of *Brugia* worms suffers from poor specificity. There is extensive cross-reactivity among filarial antigens and antigens of other helminths including the common intestinal roundworms. Further serologic tests are unable to distinguish between active and past infection. These tests still have a role in diagnosis as a negative test effectively excludes past or present infection.

TREATMENT

The use of antifilarial drugs in the management of acute lymphadenitis and lymphangitis is controversial. DEC can be given to asymptomatic children to lower down parasitemia. It also kills adult worms. Whether DEC modifies the course of disease is not proven. New agents or drug regimens are needed that would be more effective against the adult filarial worm and at the same time elicit minimal immunopathologic damage.

Currently, the major drugs used are especially effective against microfilariae. DEC is the treatment of choice and given in a 1 mg/kg as a single dose on day 1, increased to 1 mg/kg three times on day 2, on day 3 it will be 1–2 mg/kg three times and 6 mg/kg/day (in three divided doses) from days 4–14. More recently, a single dose of 6 mg/kg divided in three doses has been recognized to produce a similar therapeutic result in children with no microfilaria in the blood. Repeat doses may be necessary to further reduce microfilaremia and kill adult parasites. *W. bancrofti* is more sensitive to this drug than *B. malayi*. DEC may cause pruritus, fever, generalized body pains and hypotension; these side effects may be avoided by administering DEC in a graded, stepwise manner. This drug is also the treatment of choice for tropical pulmonary eosinophilia, a syndrome caused by circulating microfilariae.

Ivermectin may also have a role in the medical treatment of LF because it is very effective in clearing circulating microfilariae. Albendazole in high doses inhibits microfilarial production. The difficulty in management of filariasis by drugs is that late symptoms, such as elephantiasis, do not abate. The main utility of chemotherapy is in cases recognized early, before the anatomic abnormalities develop. Hydrocele can be treated surgically. Of critical importance in the management of lymphedema and elephantiasis is attention to hygiene, wearing shoes to prevent injury and reduction of lymphostasis with exercise and elevation of the lower extremity.

The more recent discovery that *W. bancrofti* harbors bacterial endosymbionts has led to use tetracycline and related antimicrobial agents as a part of the therapeutic regimen. This is under active investigation.

PREVENTION

Prevention in the past depended principally on vector. This is a difficult task since effective insecticides that also would be nontoxic to the rest of the environment are not available. Global Alliance to Eliminate Lymphatic Filariasis (GAELF) is directing a large scale LF control campaign through single dose combination of albendazole (400 mg) with either ivermectin (200 µg/kg) or DEC (6 mg/kg) in areas endemic for lymphatic filariasis.

IN A NUTSHELL

1. Filarial worms are arthropod transmitted nematodes or roundworms that dwell in the subcutaneous tissues and the lymphatics.
2. All filariae share is the unique characteristic, with defined circadian rhythm or *periodicity*, which can be nocturnal.
3. Most heavily infested areas in India are the states of Andhra Pradesh, Tamil Nadu, Kerala, Orissa, Bihar and eastern Uttar Pradesh.
4. The pathology of LF is caused principally by the adult-stage parasite; induce lymphatic dilatation that results in lymphatic dysfunction.
5. Microfilariae in peripheral blood are ingested by mosquitoes and undergo development to infective 3rd stage larvae over a period of 14 days.
6. The four most common presentations are asymptomatic (or subclinical) microfilaremia, lymphedema, hydrocele and acute attacks.
7. A definitive diagnosis of LF can be made by microscopic detection of microfilaria in the blood or occasionally from other sites such as fluid aspirated from hydroceles.
8. DEC is the treatment of choice and can be used in asymptomatic children to lower down parasitemia load.

Chapter 32.14

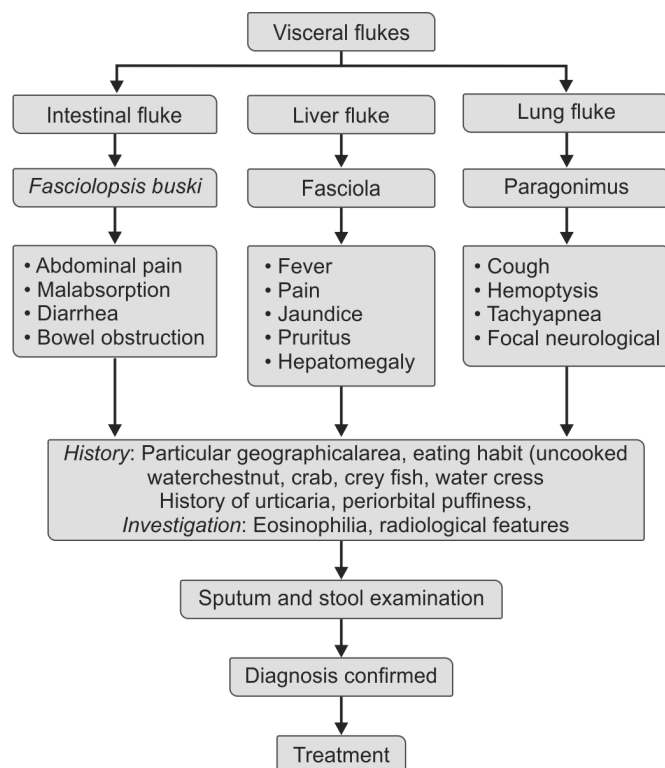

Intestinal, Liver and Lung Flukes

Vikas Jain

Trematode infections (blood flukes and visceral flukes of intestine, liver, lung) are uncommon helminthic infections. Species belonging to eight genera commonly infect human visceral organs (intestine, liver and lung). Visceral flukes are food-born zoonotic infections with complicated life cycle which are emerging as public health problem worldwide. Although most of available adult studies related to visceral flukes are reported from different Southeast Asia countries, but literature from India especially in children is usually unrecognized. It is due to ignorance and lack of medical health facilities in rural and coastal areas where these infections are common. Common visceral flukes in Southeast Asia region are **intestinal flukes** (*Fasciolopsis buski*, *Heterophyes heterophyes*, *Metagonimus yokogawai*, *Echinostoma ilocanum*), **liver flukes** (*Fasciola hepatica*, *Fasciola gigantica*, *Clonorchis sinensis*, *Opisthorchis viverrini*) and **lung flukes** (*Paragonimus westermani*) (Flow chart 1).

Visceral flukes are most commonly prevalent in rural or coastal areas where poor sociocultural food habits are conducive for transmission of these infections. Visceral flukes are commonly seen in Southeast Asia but exact data on geographical distribution of different flukes are not available. Flukes are most commonly reported from Northeast states of India. Most of Indian data are in form of case reports and case series in adults.

Flow chart 1 Approach to visceral fluke

INTESTINAL FLUKES

Fasciolopsis buski is an intestinal fluke with maximum infections occurring during late summer and early autumn. Intestinal fluke infections are commonly associated with poor socioeconomic factors such as poverty, malnutrition, lack of sanitation and tradition of eating raw or insufficiently cooked food.

Etiology

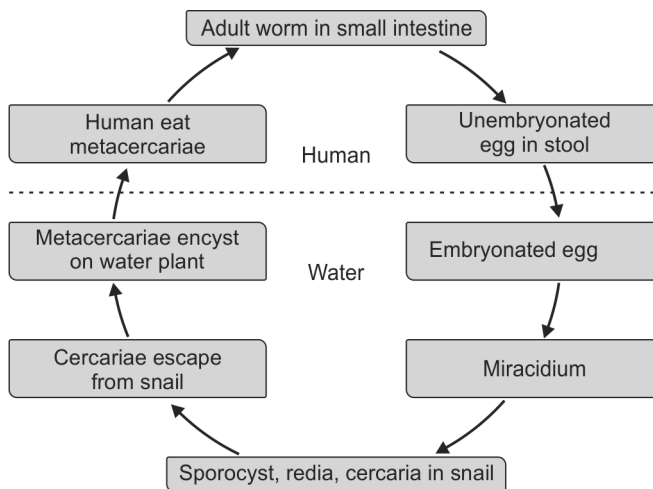

It was first described in 1843 in duodenum of Indian man by Busk. The major mode of human infection is consumption of raw or improperly cooked aquatic plants such as water chestnut, water hyacinth, water bamboo and other aquatic vegetation. Pigs are the main source of eggs and drainage of pig excreta in farms is an important factor for maintaining high endemicity. Prevalence of infection with *F. buski* in Southeast Asia countries varies from 10% in Thailand to 57% in China; data from India is sketchy.

Life Cycle

Fasciolopsis buski (giant intestinal fluke) is the largest fluke, 20–75 mm in length and 8–20 mm in width, lives in duodenum and jejunum of pigs and human where fluke lays eggs. These eggs are passed in stool and become embryonated in water in 6–7 weeks. Mature miracidia hatch from egg in water and then invade a suitable snail intermediate host, in which further developmental stages (sporocysts, rediae, cercariae) occur. Finally, cercariae escape from snail into water to encyst as metacercariae on aquatic plants. Mammalian hosts (humans and pigs) are infected if they eat these plants (Fig. 1). In the human host, metacercariae excyst and attach to duodenum and jejunum where they become adult flukes within 3 months. Life span of adult fluke ranges from 6 month to 1 year.

Pathogenesis

Adult *F. buski* produces traumatic, toxic and obstructive damage to the intestinal mucosa. It causes local mucosal inflammation along with hypersecretion of mucus, hemorrhage and ulceration. Large numbers of flukes can obstruct and even perforate the lumen. It may produce the disease by allergic mechanism due to absorption of worm metabolites in heavy infections.

Figure 1 Life cycle of *Fasciolopsis buski*

Clinical Features

Manifestations depend upon the parasitic load. Nausea, abdominal pain and diarrhea are nonspecific symptom. Heavy infections result in profuse yellow-green diarrhea with features of malabsorption due to protein losing enteropathy, vitamin B₁₂ deficiency and anemia. Large parasite load may cause bowel obstruction, acute ileus and allergic reaction due to absorption of toxic metabolites of worms. Periorbital puffiness and ascites may occur. Intestinal perforation due to *F. buski* is reported from India in a child.

Diagnosis

Complete blood count may show anemia, eosinophilia and leukocytosis. Serum albumin is low due to protein losing enteropathy. Wet stool preparation (by formalin-ethyl acetate sedimentation concentration method) shows unembryonated, ellipsoidal, 130–140 µm by 80–85 µm, operculated egg. The eggs of *F. buski* and *F. hepatica* are similar in size and shape. Exact identification of species can be done by internal transcribed spacer (ITS) sequences of ribosomal DNA. Upper gastrointestinal endoscopy may show adult fluke moving in duodenum (**Figs 2A and B**).

Management

Tetrachlorethylene, the initial drug of choice, is now replaced by praziquantel as the preferred treatment. Praziquantel is administered as a single oral dose of 15 mg/kg after evening meal or before sleep. Adverse effects include abdominal pain, headache, nausea and dizziness. Contraindication includes ocular cysticercosis and pregnancy.

Prevention

Avoid eating raw aquatic plant foods like water chestnut. Either it should be peeled off or immersed in boiling water for few minutes before consumption. Other preventive measures include sterilization of night soil before being used as fertilizer and avoiding defecation near ponds or lakes.

LUNG FLUKES

Paragonimus westermani is most common species for paragonimiasis in humans. Of late, *Paragonimus heterotremus* has also been increasingly detected in humans especially in Southeast Asia. Human paragonimiasis is caused by eating undercooked crabs, crayfish and undercooked pork. First time, it was reported in humans from Taiwan following which diagnosed worldwide

mainly in orient countries such as Japan, South Korea, Thailand, China and Philippines. In India, it is endemic in Northeast states, as in some parts of Arunachal Pradesh. First indigenous case of human paragonimiasis was reported from Manipur in 1981; subsequently 39 more patients of pulmonary paragonimiasis were described in 1986. One Indian study of 45 cases showed varied clinical presentation in children. This disease is still under reported in children due to ignorance of disease and lack of health facilities in difficult geographical area. Clinical implication of pulmonary paragonimiasis is important as it is commonly misdiagnosed as tuberculosis in Indian setting.

Pathogenesis

Paragonimus westermani is 7–12 mm in length and 4–6 mm in width, and normally resides in bronchioles in paired form where it lays eggs. Eggs are coughed out in sputum. Some eggs are swallowed in sputum which subsequently pass in stool. Eggs hatch in water and release miracidia after 2–3 weeks that invade a suitable snail intermediate host, in which further developmental stages (sporocysts, rediae, cercariae) occur. Finally, cercariae escape from snail to infect the second intermediate crustacean host (crab and crayfish) which is eaten by humans who become infected. Metacercariae excyst in duodenum and traverse through intestinal wall into abdominal cavity then migrate through diaphragm into pleural cavity and lung where they become adult worm in the vicinity of bronchiole. Life cycle of *P. westermani* is depicted in **Figure 3**. Life span of adult fluke ranges from 1 year to 20 years. During migration, it can lodge in ectopic sites like brain and skin causing cerebral paragonimiasis and migratory subcutaneous nodules respectively. Small hemorrhagic inflammatory lesions may rarely form granuloma along the migration route of immature worm which otherwise are rarely symptomatic. Clinical symptoms arise mainly due to lung and brain lesion where mature worm induces intense inflammatory reaction and cyst formation occurs. The cyst constitutes rusty fluid, eosinophils, necrotic tissue, Charcot-Leyden crystals along with adult worms and ova. Symptoms usually occur due to rupture of bronchiole releasing necrotic material and blood in sputum.

Clinical Features

Clinical manifestations depend upon parasitic load. Symptoms usually occur in pulmonary, extrapulmonary (pleural, abdominal cavity, brain and skin) and pleuropulmonary forms. Pleural effusion and migratory subcutaneous nodules are more common in children (40–50%) than adults (2%).

Figures 2A and B *Fasciolopsis buski* in second part of the duodenum on gastroduodenoscopy

Figure 3 Life cycle of *Paragonimus westermani*

Pulmonary paragonimiasis is the commonest presentation of paragonimiasis. Most children are undiagnosed or asymptomatic. Symptomatic children present with recurrent hemoptysis, cough, respiratory distress, fever and other constitutional symptoms. The disease can be easily confused with pulmonary tuberculosis. Second common manifestation is pleural effusion that varies from minimal to massive effusion depending on worm load. Skin manifestations occur in the form of migratory subcutaneous nontender, mobile nodules. These occur in 10–15% of *P. westermani* infection in children; most common sites are chest, lower abdomen, thigh and inguinal region. Other presentation like pericarditis, organomegaly and nonspecific gastrointestinal symptom can occur. Cerebral paragonimiasis is the most serious extraintestinal form which is rarely reported in children. It usually presents with fever, headache, nausea, vomiting, visual disturbance and motor weakness. In India, first case of cerebral paragonimiasis mimicking tuberculoma in a child was reported from Nagaland.

Diagnosis

Complete blood count may reveal leukocytosis with relative lymphocytosis, eosinophilia, high ESR but anemia is rare in spite of repeated hemoptysis. Chest radiography can show consolidation, cavitory lesions, pleural thickening and pleural effusion. Microscopy and immunodiagnostic test are commonly used to detect infection.

Microscopy

Wet mount smear of sputum examination shows Charcot-Leyden crystals and paragonimus eggs which are ovoid brownish yellow, unembryonated, operculated, thick shelled with size 80–120 μm by 45–65 μm . Repeated examinations of sputum along with concomitant stool examinations increase the yield in mild infection.

Serology

Immunodiagnostic test like intradermal test, Dot-ELISA, complement fixation test are commonly used. Intradermal test is done by intradermal injection of 0.01–0.1 mL of purified antigen of adult *P. westermani* on front of the forearm. Wheal diameters greater than or equal to 5 mm with erythema and pseudopodia immediately and 15 min after the inoculation indicate positive test. Negative test almost certainly rules out paragonimiasis but positive test cannot differentiate between recent and past infection, also there is cross-reaction with other trematodes. ELISA using excretory-secretory antigen (27 kDa of *P. westermani*, 31.5 kDa of *P. heterotremus*) is highly sensitive and specific for detection

of active infection. Dot-ELISA has also been used for antigen detection in sera.

Management

Pulmonary paragonimiasis is rarely life-threatening, but cerebral paragonimiasis can be fatal. The drug of choice is praziquantel (25 mg/kg three times a day for 3 days after meal). Dose in cerebral paragonimiasis is generally higher. Preventive measures include avoiding eating raw uncooked crab and crayfish, proper sanitation and public health education.

LIVER FLUKES

Liver flukes (*F. hepatica*, *Clonorchis sinensis*, *O. viverrini*) are food-borne trematode infections. In Asia, *O. viverrini* (Thai liver fluke) is commonly prevalent in Thailand, Laos, southern Vietnam, Cambodia; and *C. sinensis* (Chinese liver fluke) is common in Korea, Taiwan, China, northern Vietnam. *F. hepatica* (sheep liver fluke) is found mainly in sheep and cattle raising areas, and around 2.4 million people worldwide are infected. In India, human fascioliasis has been reported from northeastern India including Bihar, Assam, Uttar Pradesh and Mumbai.

Fasciola Hepatica

Life Cycle

Fasciola hepatica measures 30 \times 13 mm and lives in bile ducts where it lays eggs. Eggs are carried by bile into intestine and subsequently in stool. Egg after 1–2 weeks hatches in water and releases miracidia that invade a suitable snail intermediate host in which further developmental stages (sporocysts, rediae, cercariae) occur. Finally, cercariae shed their tails and encyst on water vegetation (watercress) as metacercariae. Humans become infected after eating contaminated water vegetation. Encysted metacercariae excyst in human duodenum and traverse through intestinal wall into abdominal cavity, then migrate through liver parenchyma by penetrating capsule (acute hepatic phase) and finally enter the bile ducts where they become adult worm (chronic biliary phase). Adult worm produces egg which passes in the feces through bile (Fig. 4).

Clinical Features

Manifestations depend upon parasitic load and phase of infection. Manifestations range from completely asymptomatic infection in which fluke is detected incidentally during radiological and endoscopic evaluation for unrelated disease to florid manifestations. Allergic symptoms like fever, urticaria and abdominal pain may occur during acute migratory hepatic phase during migration of larva through liver parenchyma from intestine.

Figure 4 Life cycle of *Fasciola hepatica*

This phase is usually asymptomatic and starts 6–12 weeks after eating metacercaria and lasts for weeks to months. Larvae may be found in other organs like skin, brain and lungs. In second phase when worm establishes and matures in bile duct, it causes hyperplasia of biliary epithelium and fibrosis of bile duct that lead to biliary obstruction which manifests either as recurrent biliary colic or cholangitis (fever, jaundice, pruritus and hepatomegaly). Sometimes, the adult worm may reinvade the liver parenchyma causing liver abscess. Rarely, prolonged infection can cause cirrhosis and cholangiocarcinoma in adults. It is commonly misdiagnosed as choledocholithiasis.

Diagnosis

Complete blood count may show anemia, eosinophilia and leukocytosis. Liver function test may show raised alkaline phosphatase and conjugated hyperbilirubinemia.

Microscopy Wet mount stool examination after at least 3 days of liver free diet shows unembryonated, ovoid, 130–150 µm by 63–90 µm, operculated eggs. Eggs may also be retrieved from duodenal and biliary aspirates and tissue biopsy.

Serological methods These methods are useful in both the acute and chronic phase. Fas2-ELISA detects IgG antibodies against the antigen Fas2 and fasciola excretory-secretory (ES) in serum, feces and other fluids, also no cross-reactions observed with other parasitic infection. Other closely related species such as *F. gigantica* cannot be differentiated clinically from *F. hepatica*. Animal studies have reported a higher prevalence of *F. gigantica* infection than *F. hepatica*.

Polymerase chain reaction (PCR)-restriction fragment length polymorphism (RFLP) A simple PCR-RFLP assay, using the restriction enzymes *Ava*II and *Dra*II based on a 618-bp-long sequence of the 28S rRNA gene is described for the diagnosis of fascioliasis and also can differentiate between *F. hepatica* and *F. gigantica* infection.

Others Ultrasonography may show focal lesion in liver, dilated biliary radicles, biliary wall thickening and sometime echogenic worm. Endoscopic ultrasonography is good modality to screen lower common bile duct. If suspicion is high, endoscopic retrograde cholangiopancreatography (ERCP) may be useful for diagnostic and therapeutic intervention. Abdominal CT in the acute migratory phase reveals multiple small hypodense lesions and chronic phase may reveal hyperintense lesions 10–20 mm in diameter, which represents calcified dead flukes in the bile ducts, liver capsule thickening.

Management and Prevention

Triclabendazole is the drug of choice, administered as a single oral dose of 10 mg/kg, it acts by inhibiting protein synthesis, it has few side effects. Oral bithionol (30–50 mg/kg on alternate day for 10–15 doses) is also recommended but both drugs are not easily available. Praziquantel (25 mg/kg/day for 2 days after meal) is an alternative but resistance has been reported. Child may require endoscopic intervention in the form of endoscopic retrograde cholangiopancreatography with sphincterotomy for drainage of bile to relieve cholangitis. Rarely surgical intervention may be needed.

IN A NUTSHELL

1. Most common species of visceral flukes include *Fasciolopsis buski* (intestinal fluke), *Paragonimus westermani* (lung fluke), and *Fasciola hepatica* (liver fluke).
2. Humans are accidental intermediate hosts. Infection is acquired by eating uncooked aquatic water plant (*Fasciolopsis* or *Fasciola*), or crustaceans (*Paragonimus*).
3. Clinical features pertain to the primary organ where the fluke resides.
4. Diagnosis is established by documentation of eggs in wet stool; and endoscopy (*Fasciolopsis*), sputum examination (*Paragonimus*), or duodenal aspirate (*Fasciola*).
5. Drug of choice is Praziquantel for intestinal and lung flukes; and triclabendazole for the liver fluke.

Chapter 32.15

Tapeworm Diseases

Ruchi Rai

Cestodes or tapeworms are segmented tape like worms which cause clinical disease in man. Humans are definitive hosts for all tapeworms with the exception of *Echinococcus* species, sparganosis and coenurosis. The infection with cestodes is common in India and other developing countries as the spread is facilitated by poor standards of hygiene. The infection gets transmitted by feco-oral route or ingestion of poorly cooked meat or fish. Medically important tapeworms are listed in **Box 1**.

BOX 1 Tapeworms causing disease in humans

- *Diphyllobothrium latum* (fish tapeworm)
- *Taenia solium* (beef tapeworm)
- *Taenia saginata* (pork tapeworm)
- *Echinococcus granulosus* (dog tapeworm)
- *Echinococcus multilocularis*
- *Hymenolepis nana* (dwarf tapeworm)
- *Hymenolepis diminuta* (rat tapeworm)
- *Dipylidium caninum*
- *Sparganum mansoni*; *S. proliferum*
- *Multiceps*

TAENIA SOLIUM (PORK TAPEWORM)

The infection is seen worldwide but incidence is high in countries of Africa, Latin America, East Europe and South East Asia especially, India. In 2003, World Health Assembly declared that *T. solium* is of worldwide public health importance. Intestinal infection is usually not seen in vegetarian population and those not consuming pork. The tissue cysticercosis can be acquired by vegetarians through contaminated water or vegetables. *Taenia asiatica* is a sister species of *Taenia saginata* found in Asia which causes similar illness in humans with pigs acting as intermediate host.

Etiology

T. solium is also known as pork tapeworm as pigs are the intermediate host. Both the adult and the larval stages cause clinical disease in humans. The pigs get infected by ingesting fecal matter of humans containing eggs or proglottids of *Taenia*. The ova are ingested by the pigs and hatch into an embryo or oncosphere. These oncospheres, with the help of their hooklets penetrate the intestinal wall of the pig and reach the systemic circulation. They finally get lodged in the striated muscles and with time, evolve into mature larva or cysticercus cellulosae. The cysticerci are visible as tiny white dots in the infected pork (measly pork). Humans get infected when they eat raw or inadequately cooked pork. The head or the scolex (**Fig. 1**) emerges from the cysticercus and attaches to the intestinal wall and gradually develops into an adult tapeworm. The adult worm may be several meters long (up to 25 m) (**Fig. 2**). The adult worm has segments or proglottids which shed eggs in the stool. The humans can also get infected by the larval form by ingestion of eggs through contaminated water or vegetables, which leads to tissue cysticercosis in the same way as in pigs. Life cycle of *Taenia* is depicted in **Figure 3**.

Pathogenesis

The adult worm may compete with the child for nutrition or there may be a possibility of mechanical obstruction of the gut. The proglottids also escape from the anus leading to local symptoms. The cysticercosis may affect any organ or tissue of the body. The body responds to the

**Figure 1** Scolex of *Taenia solium*

Source: Public Health Image Library (PHIL), CDC, USA.

**Figure 2** Adult tapeworm; *Taenia saginata*

(Source: Public Health Image Library (PHIL), CDC, USA)

cysticerci by a tissue inflammatory and granulomatous response. Over a period of months to years the host response may lead to either resolution or calcification of these cysticerci.

Clinical Features

In spite of the length of the worm, children remain mostly asymptomatic or may have mild and vague symptoms. Some children may complain of abdominal discomfort or diarrhea. There may be loss of appetite and weight. Intestinal obstruction and appendicitis have rarely been reported. There may be anal pruritis because of the proglottids crawling out of the anus. Cysticercosis leads to symptoms which vary depending on the site of lodgment of the cysticerci and host response. The symptoms may take months to years before manifesting after infection is acquired. The cysticercosis may involve skin or subcutaneous tissue or less commonly eyes, lungs, liver and spinal cord, etc. Involvement of brain, i.e., neurocysticercosis is a serious complication of this infection. This is discussed in detail elsewhere in the book.

Diagnosis

Microscopic examination of the stool may demonstrate the eggs of *Taenia* (**Fig. 4**), but species cannot be identified from the eggs.

Figure 3 Life cycle of *Taenia*

Source: Public Health Image Library (PHIL), CDC, USA.

Species can be identified only on examination of the proglottids, pressed between two microscopic slides and using a hand lens. Available serologic tests are not helpful in diagnosis of intestinal infection. DNA based differentiation between the two species (i.e., *solium* and *saginata*) has been tried using probes, polymerase chain reaction (PCR) with species specific primers and PCR followed by restriction enzyme analysis (PCR-REA), but are also only of research value. The Tso31 nested PCR in stool samples has been found to be sensitive and specific. Tissue cysticercosis can be diagnosed by biopsy of the tissue which shows the scolex with suckers and hooks. Ocular cysticercosis can be diagnosed by ophthalmoscopy.

Treatment and Prevention

Praziquantel is an effective drug for treatment. It is used as a single oral dose of 5–10 mg/kg. Niclosamide can also be used as single dose therapy in dose of 50 mg/kg oral dose. Nitazoxanide has been found to be effective in children not responding to praziquantel and niclosamide. Purgatives can be given with praziquantel to expel out the dead worm, otherwise it gets absorbed after being killed. Proper sanitation, good animal rearing practices and proper sewage disposal measures are effective in preventing infection. Pork should be carefully examined and consumed after adequate cooking.

TAENIA SAGINATA (BEEF TAPEWORM)

This tapeworm is also known as beef tapeworm as cattle act as the intermediate host. The life cycle, pathogenesis, clinical features and treatment of *T. saginata* are similar to that of *T. solium*. The infection

Figure 4 Egg of *Taenia* sp. under high magnification of 400X
Source: Public Health Image Library (PHIL), CDC, USA.

occurs by ingestion of raw or under cooked beef. Human infection is not possible with ingestion of eggs and no tissue cysticercosis occurs. Diagnosis is made by examining the proglottids and can be differentiated from those of *T. solium* by counting the number of lateral uterine branches in the gravid segments. The count in the segments of *T. saginata* is more than 13 and that in *T. solium* is less than 13.

DIPHYLLOBOOTHRIUM LATUM (FISH TAPEWORM)

Disease caused by infection with *Diphyllobothrium latum* is seen in parts of Europe, Japan and North America. Rare cases have been reported from Indian Subcontinent.

Etiology

This is the longest tapeworm to infect man. Man is the definitive host and the parasite has two intermediate hosts. The adult worm sheds up to a million eggs each day which are passed in the stools of infected children. The eggs are not infective to humans. When these eggs reach fresh water due to contamination with human feces, they hatch into first stage larva (coracidium). These larvae are ingested by crustaceans (*Cyclops*) which are the first intermediate hosts. These *Cyclops* are in turn eaten by fresh water fish which act as the second intermediate host. Here they transform into the second stage larva (proceroid larva). Consumption of raw or improperly cooked fish by children leads to infection. Life cycle is depicted in **Figure 5**.

Pathogenesis

Diphyllobothrium latum competes with the host for vitamin B₁₂ in the ileum and also interferes with its absorption from the diet. There is also parasite mediated dissociation of the vitamin B₁₂-intrinsic factor complex in the gut. This interference with vitamin B₁₂ is racially determined and commonly seen in Finland. It is also postulated that the strains found in Finland absorb more vitamin B₁₂ than strains elsewhere.

Clinical Features

Nonspecific abdominal symptoms are seen in children. They may complain of loss of appetite, vomiting, fatigue, weakness and weight loss. Megaloblastic anemia is the only significant clinical manifestation (bothriocephalus anemia). Vitamin B₁₂ levels may be low in many infected children, but clinically significant anemia is seen in very few ($\approx 2\%$). Other features of megaloblastic anemia like leukopenia, thrombocytopenia, signs of peripheral neuropathy and degeneration of the posterior column of spinal cord are also present. The anemia becomes more significant in children with other co-existing causes of megaloblastic anemia.

Management

Diagnosis can be easily made by examination of the stool for eggs. The eggs are found in abundance in stool of infected children and are different from eggs of other tapeworms. Praziquantel is the drug of choice in a single oral dose at 5–10 mg/kg. Niclosamide is also an effective drug. Vitamin B₁₂ deficiency improves with the treatment of infection and supplementation with the vitamin. The disease can be prevented by improved sanitation and consumption of properly cooked fish. Freezing fish at -20°C for 7 days also kills the larva and prevents infection.

ECHINOCOCCUS GRANULOSUS (DOG TAPEWORM)

This zoonosis is one of the exceptions where humans are not the definite host. Humans act as intermediate hosts and the disease

Figure 5 Life cycle of *Diphyllobothrium latum*
Source: Public Health Image Library (PHIL), CDC, USA.

caused is known as cystic hydatid disease. Other members of the *Echinococcus* species are *E. multilocularis* which causes alveolar echinococcosis and *E. oligarthrus* causes polycystic echinococcosis. Details are in the next chapter.

HYMENOLEPIS NANA (DWARF TAPEWORM)

It is a very common infection among children spread by feco-oral route. It is the only cestode which does not require an intermediate host. It is very small in size (≈ 2 cm) and thousands of these worms inhabit the intestines of the host. Usually causes no symptoms or minor symptoms like abdominal pain and anorexia. Diagnosis is by demonstration of eggs (**Fig. 6**) in stools. Drugs used for treatment are praziquantel and nitazoxanide.

Figure 6 Egg of *Hymenolepis nana*
Source: Public Health Image Library (PHIL), CDC, USA.

IN A NUTSHELL

1. Tapeworm diseases are common in humans, especially in children. The infection is seen all over the world.
2. Transmission of infection occurs by feco-oral route (tissue cysticercosis) or by ingestion of raw or poorly cooked meat or fish (adult worm).
3. Most of the adult worm infection causes no significant symptoms.
4. Infection by larval stage can cause serious manifestations like neurocysticercosis and echinococcosis.
5. Intestinal infections are easy to treat. Infection by larvae also responds well to drugs where the drugs need to be given for a longer duration.
6. Prevention of infection is possible by improving standard of hygiene, provision of safe drinking water and proper inspection and cooking of meat.

Chapter 32.16

Hydatid Disease: Echinococcosis

SK Gupta

Hydatid disease is a parasitic infestation caused most commonly by *Echinococcus granulosus* tapeworm. The other responsible species are *Echinococcus multilocularis* and *Echinococcus vogeli*. The disease is endemic in many sheep and cattle raising countries such as Australia, Africa, Middle East and Latin American countries. However, the disease has spread to non-endemic regions also and has become a global health problem. Man is an accidental host and a *dead-end* for the parasite.

LIFE CYCLE

Echinococcus granulosus is a cestode, the adult form of which is 3–6 mm long and resides in the small intestine of the definitive host. The definitive hosts are usually dogs and other canines. The gravid proglottids present in the definitive host release eggs which pass into their feces. These eggs, then ingested by the intermediate host such as cattle, sheep, goat, etc., release an oncosphere larva in the small bowel of the intermediate host which penetrates the intestinal wall and enters the blood or the lymph vessels. It can then reach various organs particularly the liver (which acts as the first filter) and the lungs (the second filter). On reaching these organs, the oncosphere larva develops into the hydatid cyst (metacestode larvae). The hydatid cyst has two layers, the inner nucleated germinal layer known as the endocyst and an outer acellular layer called the ectocyst. The ectocyst is in turn surrounded by a host derived fibrous layer called the pericyst. The germinal layer gives rise to brood capsules and protoscolices. The brood capsules can detach from the germinal layer and give rise to daughter cysts that fill the cyst cavity. The definitive hosts get infected by eating the offal of the intermediate host which contains viable protoscolices. After ingestion, the protoscolices evaginate and attach to the canine intestinal mucosa. They attain the adult stage (sexual maturity) in 4–6 weeks.

Human beings are an accidental host and a *dead-end* for the parasite. They get infected by coming into contact with infected dogs, the mode of transmission being through the fecal-oral route. *Echinococcus multilocularis* has a similar life cycle with the difference that definitive hosts are fox and to lesser extent dogs, coyotes and wolves and the intermediate hosts are small rodents.

PATHOGENESIS

The disease mostly affects the liver in adults but in children pulmonary hydatidosis is more common. Combined lung and liver involvement is more common in children than in adults. Hydatid disease can affect almost any organ in the human body and consequently has myriad presentations depending upon the organ of involvement. Since it is a slow growing disease, it is usually asymptomatic in the initial phase and by the time symptoms manifest the hydatid cyst has grown to a considerable size. It is important to be aware of this disease because it forms the differential diagnosis of space occupying lesion in many organs. It is usually amenable to a combination of surgical and medical treatment but can recur and at times can be life-threatening.

CLINICAL FEATURES

The initial phase of primary infection is almost always asymptomatic. The small cysts which are formed initially remain

asymptomatic for many years and become symptomatic only when they become large. Hydatid disease is usually diagnosed in adult patients because of the slow growing nature of hydatid cyst (ranging from 1 cm to 5 cm in diameter per year). Only 10–20% of cases are diagnosed in patients younger than 16 years of age.

Cerebral and ocular hydatid cysts can become symptomatic even when they are small in size hence most cases of cerebral and ocular echinococcosis are diagnosed in the pediatric age group. Symptoms can also be precipitated if the cysts rupture as the hydatid cyst fluid is allergenic and may cause anaphylaxis. Apart from the liver and lungs, hydatid disease can affect almost any organ which includes (but not limited to) brain, eyes, heart, kidney, spleen, pancreas, salivary glands, breast, bone and muscles. The clinical presentation would therefore depend upon the organ of involvement, the size of the cyst, the mass effect within the organ and upon surrounding structures and complications relating to cyst rupture and secondary infection.

Liver Hydatid Disease

It usually presents as pain in the right upper quadrant with or without jaundice. The child may also complain of nausea and vomiting. There may be a history of fever if the cyst gets infected. In large hydatid cysts, abdomen may be distended and there is a palpable liver which is usually smooth, firm and non-tender. Sometimes a liver hydatid cyst may mimic a palpable gall bladder. If the cyst ruptures intraperitoneally, allergic reaction ranging from mild anaphylaxis to a fatal reaction can be precipitated. Multiple intraperitoneal hydatid cysts (presenting as multiple palpable abdominal lumps) can result from rupture of liver hydatid cyst. More commonly, these patients present as acute abdomen with abdominal pain, vomiting, distension and absent bowel sounds. In such cases, it is difficult to differentiate it from ruptured liver abscess. A detailed and thorough clinical history will usually provide clues to the diagnosis. The liver hydatid cysts can also rupture into the biliary tree leading to cholangitis and/or biliary obstruction by daughter cysts.

Pulmonary Hydatidosis

It presents with cough, mucopurulent sputum, fever, chest pain and dyspnea. Hemoptysis is another presenting symptom. These are more common in males than in females and can be unilateral or bilateral. The right lung is more commonly involved. In the lungs, ruptured cyst membranes may be expectorated out through a broncho-pulmonary fistula or can be retained to act as a nucleus for bacterial or fungal infection. Rupture of hydatid cyst can result in dissemination of protoscolices leading to multiple secondary echinococcosis. Alveolar echinococcosis (caused by *Echinococcus multilocularis*) usually presents later than the cystic form. They have an initial asymptomatic period ranging from 5 years to 15 years followed by a chronic form. If left untreated they have high mortality rate.

A diagnosis of hydatid disease should be kept as a possibility in the presence of a cystic mass in a person with history of exposure to sheep or dogs in areas where *Echinococcus granulosus* is endemic. These must be differentiated from benign cysts, abscesses, cavitory tuberculosis, fungal infection and benign or malignant neoplasms.

INVESTIGATIONS

The diagnosis of hydatid disease can mostly be established by the combined use of noninvasive radiological imaging and immunodiagnostic tests. Eosinophilia, which was also considered to be of value in the diagnosis of hydatid disease, is positive in less than 25% of infected persons.

Imaging

The most commonly used imaging modality for the diagnosis of hydatid disease of the liver is abdominal ultrasonography. It gives an accurate delineation of the site, size and number of hydatid cysts. It also gives a reasonably accurate assessment of the vitality of the hydatid cyst. The World Health Organization (WHO) has developed a classification system for hepatic cysts identified by ultrasonography (**Box 1**).

CT scan is the modality of choice for pulmonary and cerebral hydatidosis, whereas MRI is the preferred imaging modality for hydatid cysts involving the muscles, salivary glands and retroperitoneum. CT abdomen is also helpful in more accurate localisation of liver hydatid cysts in relation to the segmental anatomy of the liver.

Serology

Antibody assays are useful to confirm diagnosis in patients with presumptive radiological diagnosis even though a fair number of patients with cystic echinococcosis will not have a detectable immune response. Hepatic cysts are more likely to demonstrate a positive immunological test than the pulmonary hydatid cysts. The likelihood of a positive serological test is inversely related to the degree of sequestration of echinococcal antigens within the cyst cavity. Thus, intact cysts are unlikely to demonstrate a positive immune reaction, whereas cysts that have previously ruptured or leaking cysts will have a positive immunological test. Amongst the various immunological tests described, Casoni's test which is a type of immediate hypersensitivity reaction is positive only in approximately 60% of cases. It is also falsely positive in other parasitic infections. The indirect hemagglutination test is sensitive, but enzyme linked immunosorbent assay (ELISA) is more accurate and is the preferred diagnostic test for initial screening. Specific echinococcal antigens can be demonstrated by immunoblot assays but are not commonly used.

Aspiration

In seronegative individuals, percutaneous aspiration of the cyst under ultrasonographic guidance and the demonstration of protoscolices or hydatid membranes are confirmatory. This test is associated with a small risk of anaphylaxis and the need to treat such a reaction should be anticipated. It is also advisable to start anthelmintic treatment before carrying out the aspiration. In patients with pulmonary hydatidosis, protoscolices can be demonstrated in sputum or bronchial washings.

TREATMENT

Till the 1980s, surgery was considered to be the only modality for treatment of echinococcal cysts. However availability of more efficacious anthelmintic treatment with newer benzimidazole compounds have supplemented and in some cases replaced

surgical treatment. More recently, treatment with percutaneous cyst aspiration, injection of scolical agents and re-aspiration (PAIR) has been introduced with success. The various treatment options have been reviewed by the WHO Informal Working Group on Echinococcosis (**Table 1**).

Surgery

Complete surgical removal of the intact hydatid cyst is the definitive treatment resulting in complete cure (**Figs 3 and 4**). The aim of surgery is complete removal of the cyst without spilling the cyst contents and is best achieved by pericystectomy. The plane of surgical resection lies between the ectocyst (the outer layer of the hydatid cyst) and the pericyst (which is the layer of compressed host tissue). Other surgical procedures such as simple drainage, capitonnage, marsupialization (de-roofing) and resection of the involved organ may be used depending upon the location of the cyst. A more radical surgical procedure is associated with a higher operative risk but a lesser likelihood of recurrence and *vice-versa*. Whenever lesser surgical procedures are being used, adjunctive anthelmintic treatment should always be given. Surgery is the

BOX 1 WHO Classification for hepatic hydatid disease

- CL—Unilocular cysts with uniform anechoic content (but without any pathognomonic signs)
- CE1—Unilocular cyst with uniform anechoic content but with the presence of pathognomonic signs such as visible cyst wall and snowflake sign
- CE2—Multivesicular, multiseptated cysts (**Fig. 1**)
- CE3—Anechoic content with detachment of laminated membrane from the cyst wall visible as a floating membrane or *water-lily sign* (**Fig. 2**)
- CE4—Heterogeneous hypo- or hyper-echoic degenerative content without any visible daughter cysts
- CE5—Cysts characterized by thick calcified wall producing a cone-shaped shadow. The calcification may be partial or total.

TABLE 1 Treatment of hydatid cyst according to the WHO staging

WHO staging	Ultrasound picture	Treatment
CE1	Uniformly anechoic cyst with fine echoes settled representing hydatid sand	<5 cm Albendazole alone >5 cm Albendazole + PAIR
CE2	Multiseptate honeycomb cyst	Surgery + Albendazole
CE3	Cyst with detached membranes	<5 cm Albendazole alone >5 cm Albendazole + PAIR
CE4	Cysts with heterogeneous hypo/hyperechoic contents and no daughter cysts	Wait and watch
CE5	Solid and calcified walls	Wait and watch

preferred treatment for large liver cysts (> 10 cm in diameter), if the cysts are secondarily infected, or if they are located in certain organs such as lung, kidney or brain.

There is a definite risk of anaphylaxis during surgical intervention and can be minimized by instilling scolicalidal agents in the cyst cavity intraoperatively. These include 10% formaldehyde, 3% hypertonic saline and 10% povidone-iodine. Formaldehyde is not used nowadays because of the risk of severe sclerosing cholangitis if cyst-biliary communications are present. It is also prudent to pack the abdominal contents by pads soaked in 10% povidone-iodine to prevent dissemination of the protoscolices during surgery. Surgery is contraindicated in patients who are at poor surgical risk or have multiple cysts that are difficult to access. Operative mortality ranges from 0.5% to 4% and is higher in patients undergoing reoperations.

Chemotherapy

Anthelmintic treatment with benzimidazole compounds can be used as the sole modality of treatment in simple hydatid cysts less than 1 cm in diameter or as an adjunct to surgery. Nearly a one-third of the patients so treated demonstrate a complete and permanent disappearance of the cyst while nearly 50% show a significant reduction in the cyst size. However, nearly 20–40% of patients do not show a favorable response. Medical treatment is not useful in complicated multiseptated cysts or cysts with thick and calcified cyst wall. Both albendazole (10–15 mg/kg/day) and mebendazole (40–50 mg/kg/day) have been used with good results. Albendazole is better than mebendazole because of its better absorption from the intestine and penetration into the cyst cavity. The minimum duration of treatment is 3 months. Adverse reactions in the form of neutropenia, hepatotoxicity, alopecia, etc., can occur but these are reversible. Pregnancy, chronic liver disease and bone marrow depression are contraindications for medical treatment. Praziquantel has also been used in different regimens (50 mg/kg daily, once weekly, or once every two weeks). A combination of praziquantel plus albendazole is superior to albendazole alone.

PAIR

It consists of Percutaneous puncture (under sonographic guidance), Aspiration of the cyst contents, and Injection of scolicalidal agent (95% ethanol or hypertonic saline) for at least 15 minutes and Re-aspiration (PAIR). This is a relatively newer option for the treatment of hydatid cysts particularly those of the liver. This technique is useful for patients with smaller cysts and for those who either cannot undergo or refuse surgery. PAIR is contraindicated for inaccessible or superficially located liver cysts

Figure 3 Operative photograph showing a daughter cyst within the opened cyst cavity in the liver

Figure 4 Operative photograph showing multiple daughter cysts evacuated from a liver hydatid cyst

Source: Professor AN Gangopadhyaya, Department of Pediatric Surgery, Institute of Medical Sciences, BHU, Varanasi.

and for inactive or calcified cystic lesions. It is best used for single or multiple cysts in the liver, spleen, kidney and the abdominal cavity. In view of the risk of sclerosing cholangitis, PAIR should not be used in liver cysts with cyst-biliary communication as evidenced by presence of bilirubin in the cyst fluid or by endoscopic retrograde cholangiopancreatography (ERCP) and/or operative cholangiogram. It is preferable to do PAIR under anthelmintic coverage which should be continued for at least one month after the procedure. A meta-analysis of PAIR combined with anthelmintic treatment has shown better clinical efficacy, lower morbidity and mortality and a shorter hospital stay than surgery.

Follow-up

Objective response to treatment is best assessed by ultrasonography, computed tomography or magnetic resonance imaging. These should be done at intervals of 3 months and should be continued for at least 3 years.

PREVENTION AND CONTROL

The earliest successful control program was launched in Iceland and resulted in eradication of the disease. Health education which led to elimination of home slaughter of sheep was the sheet anchor of this program. Similar programs based on education of rural populations and prohibition of farm slaughter (backed by legislative action) were initiated in New Zealand and Tasmania and resulted in the gradual elimination of transmission.

IN A NUTSHELL

1. Hydatid disease is a zoonoses caused by the cestode tapeworm, *Echinococcus granulosus* and *Echinococcus multilocularis*.
2. Man is an accidental host and gets infected by the fecal-oral route while coming in contact with infected dogs and sheep.
3. Hydatid disease can affect almost any organ of the body. However, liver and lungs are the most commonly affected organs.
4. Hydatid cysts are slow growing and usually present late. Clinical features depend upon the location, size and nature of the cyst.
5. Noninvasive imaging modalities combined with immunological tests are diagnostic.
6. Surgery is the mainstay of treatment for the vast majority of hydatid cysts. Medical treatment is a necessary adjunct of surgical treatment and can be used as the sole modality for simple, isolated cysts.
7. PAIR is a relatively newer technique which has shown better results than surgical treatment in cases of hydatid cysts of the liver and other intra-abdominal organs.

Chapter 32.17

Schistosomiasis

Ritabrata Kundu, Devdeep Mukherjee

Schistosomiasis (bilharziasis) is a parasitic disease caused by trematode worms of the genus *Schistosoma*. Humans are primarily affected by five species: *Schistosoma mansoni*, *Schistosoma japonicum*, *Schistosoma haematobium*, *Schistosoma intercalatum*, and *Schistosoma mekongi*.

EPIDEMIOLOGY

Although not commonly seen in India, Schistosomiasis remains a major cause of mortality for the developing regions of Africa, South America, the Caribbean and the Middle East. In Asia, it is more commonly seen in Cambodia and Laos. Globally, it is the third highest cause of morbidity after malaria and intestinal helminthiasis. Schistosomiasis is endemic in 74 countries. World over, almost a billion people are at risk of infection and close to 300 million people are infected with the parasite. The disease burden is contributed by the three major species affecting humans (*S. mansoni*, *S. haematobium*, and *S. japonicum*). It is estimated to be close to 25 million DALY (disability adjusted life years). The disease is more commonly seen in developing countries having areas with poor hygiene. Children bathing or swimming in water contaminated with the infective stage of the parasite (cercariae) are more commonly at risk.

LIFE CYCLE

The life cycle involves humans or animals as the definitive host and a snail as an intermediate host. The definitive host gets infected on exposure to cercariae contaminated fresh water (Fig. 1).

Sexual phase Cercariae penetrate through the host skin by releasing glandular secretions, lose their tails and transform into schistosomula (young schistosomes). After two days, the schistosomula penetrate through the dermis and then the endothelium of blood vessel to be carried to the lungs where they may reside for many days. Finally they reach the liver and begin feeding on red blood cells. They undergo maturation and mate within the liver vessels and finally come out as male and female worms and penetrate more commonly the portal or the pelvic vessels. The only exception is *S. haematobium*, which penetrates the urinary bladder venous plexus. The females lay eggs within the blood vessels they inhabit. The eggs are carried within the blood vessels to the liver where they are lodged within the presinusoidal portal venules. Few eggs may reach the intestines and are passed with feces (Fig. 2). Eggs of *S. haematobium*, however reach the urinary bladder and are passed with urine.

Asexual phase The eggs hatch into miracidia (ciliated larval forms) on coming in contact with water. This miracidia then enters the snail where it transforms into cercariae to complete the asexual phase of development. The cercariae are finally released to complete the life cycle.

CLINICAL FEATURES

The clinical features mainly depend on the site of infection by the parasite. However, it can be broadly classified into an acute form and a chronic form of the disease. *Acute* (Katayama syndrome) disease occurs within a few weeks of infection; *Chronic* (most common form) may manifest after months or years after infection.

Katayama Syndrome

A serum sickness like syndrome, whereby antigens are liberated and cause a T helper type 1 cell mediated inflammatory response along with the liberation of several interleukins (IL-1 and IL-6) and tumor necrosis factor (TNF). Clinical features include fever,

Figure 1 Life cycle of *Schistosoma*

Source: Public Health Image Library (PHIL), CDC, USA.

1. *Schistosoma mansoni* 2. *Schistosoma haematobium* 3. *Schistosoma japonicum*

Figure 2 Eggs of *Schistosoma*

Source: Public Health Image Library (PHIL), CDC, USA.

malaise, cough, generalized body ache, abdominal pain, blood in stool, and an erythematous, maculopapular rash. The symptoms may resolve spontaneously in a few weeks without treatment. However it is extremely imperative to treat these patients to prevent them from developing chronic schistosomiasis.

Chronic Schistosomiasis

Following inadequate treatment, the parasites may remain in the body resulting in chronic schistosomiasis. A T helper type 2 cell mediated granulomatous reaction along with the liberation of interleukins (IL-4, IL-5, IL-13) and cytokines result in fibrosis of tissues. Type 1 T helper (Th1) cells also has a role in granuloma formation. The immunological reaction causes organ injury but fails to destroy the parasites. Manifestations depend on the site of invasion by parasite:

Gastrointestinal Abdominal pain, dysentery, hepatomegaly, periportal fibrosis, splenomegaly, ascites, prominent abdominal blood vessels, esophageal varices and portal hypertension.

Urogenital Cystitis, dysuria and hematuria are commonly seen. In advanced cases we may see damage to the kidneys, ureters and bladder. Genital lesions are common and patients may develop irreversible infertility. Co-infection with HIV hastens the progression of the viral infection. *S. haematobium* is also notorious for causing squamous cell carcinoma of the urinary bladder.

Heart and lungs Persistent cough, hemoptysis, wheeze and breathlessness may occur following infection.

Central nervous system Patients may complain of headache and dizziness. Lumbosacral myelopathy characterized by loss of power and sensation in lower limbs is seen. Convulsions can also occur. Patients may simply present with a space occupying lesion in the brain or spinal cord. Neurological involvement is reported in 5% of cases.

LABORATORY INVESTIGATIONS

Stool and Urine

Stool (for *S. mansoni*, *S. japonicum*, *S. mekongi* and *S. intercalatum* eggs) or urine samples (for *S. haematobium* eggs) are examined microscopically for parasite eggs. These are the gold standard investigations to diagnosis Schistosomiasis. The eggs of *S. mansoni*, *S. japonicum*, *S. mekongi*, and *S. intercalatum* are shed with stool. These can be detected by the Kato-Katz technique or the Ritchie technique. Eggs of *S. haematobium* are shed in urine. Routine urine examination will show evidence of hematuria. Diagnosis of *S. haematobium* can be performed by filtration technique using paper, nylon or polycarbonate filters.

Serologic Tests

Since the eggs are shed infrequently and in small amounts, it is at times necessary to establish the diagnosis by serologic testing. It is especially essential for people living in nonendemic regions and in areas of low transmission. This test helps in identifying exposure to infection and also guides on extent of treatment required.

Antigen Detection Methods

Advances have been made in isolating antigens of parasites from the body. Monoclonal antibodies have been used to detect parasite antigens in blood and urine. Few other antigen detection methods are the circulating anodic antigen (CAA) and circulating cathodic antigen (CCA).

Antibody Detection Methods

Serum samples are examined by FAST-ELISA using *Schistosoma mansoni* adult microsomal antigen (MAMA). A reaction greater than 9 units/ μ L serum is termed positive for infection with *Schistosoma* species. The sensitivity of the above test however declines for species apart from *S. mansoni*. Immunoblots of *S. haematobium* and *S. japonicum* can be utilized for diagnosis.

TREATMENT AND PREVENTION

Praziquantel is the drug of choice. Efficacy is however dependent on dose: 60 mg/kg/day in 3 divided doses for *S. japonicum*, *S. mekongi*; and 40 mg/kg/day in 2 divided doses *S. mansoni*, *S. haematobium*, *S. intercalatum*. Duration of treatment is for 1–2 days.

Artemisinin derivatives (artesunate and artemether) have been used for prevention. Several doses when administered at weekly or bi-weekly intervals result in increasing the protection rates as a result of its killing of juvenile schistosomula. The combination of praziquantel and artesunate have a greater protection rate against Schistosomiasis.

IN A NUTSHELL

1. Schistosomiasis is caused by trematode worms of the genus *Schistosoma*. Humans are primarily affected by five species: *Schistosoma mansoni*, *Schistosoma japonicum*, *Schistosoma haematobium*, *Schistosoma intercalatum*, and *Schistosoma mekongi*.
2. It has an acute and a chronic (more common) course.
3. Isolated commonly through urine and stool specimens.
4. School going children are more at risk following swimming in parasite infested water or drinking water contaminated with cercariae.
5. Praziquantel is the drug of choice.

Section 33 FUNGAL INFECTIONS

Section Editor Piyush Gupta

Chapter 33.1

Fungi

VG Ramachandran, Piyush Gupta

Out of about 100,000 species of fungi, approximately 200 or so are known to cause infection in man and animals. Fungal infections are also known as *mycoses*. Mycoses are recognized less frequently than bacterial, viral, and parasitic infections but constitute a significant cause of morbidity and mortality worldwide. Some of the fungi are geographically restricted but majority are found globally. Fungal diseases are known to occur as localized outbreaks but have not been reported in the form of an epidemic.

In recent times, fungi have emerged as important agents of opportunistic infections. The compromised host is at increased risk of severe systemic mycotic infections as a result of congenital or acquired immune deficiencies, malignancies, metabolic disorders, and following transplantation or chemotherapy. Increased life expectancy has had its fall-out, with aged patients being more susceptible to secondary fungal infections than the younger individuals.

Mycoses are primarily acquired and classified as cutaneous, mucocutaneous and pulmonary with respect to their site of infection. They are usually not transmitted from person to person except the dermatophytoses. Fungal infections are also not sexually transmitted with the exception of candidal balanoposthitis and rarely blastomycosis and histoplasmosis.

Some fungi are toxic and their ingestion may result in serious clinical manifestations (mushroom poisoning or mycetismus). Some other fungi produce toxins such as aflatoxin, muscarine,

rubratoxin, etc. Some fungal species act as allergens and cause allergic manifestations. **Table 1** lists a few of the common fungal infections and their causative organisms.

Chapter 33.2

Antifungal Therapy

Arunaloke Chakrabarti, Prashant Sood

Medical advancements in neonatology, pediatric immunodeficiency disorders, hematology, oncology and transplantation have substantially reduced the mortality and morbidity in children. These advancements are intimately linked with widespread use of antibiotics, immunomodulators including steroids and invasive technologies. These strides in pediatric practice and in general modern medicine have given rise to a growing population of children highly vulnerable to invasive and noninvasive fungal infections. There has been a 307% rise in fungal infection burden in adults and children between 1979 and 2000. Fortunately, antifungal development has kept pace with their growing need. This is all the more pertinent because fungi are eukaryotic microorganisms with several biosynthetic and genetic similarities with humans. This poses a formidable challenge to exploit fungus-specific metabolic differences for devising antifungals. Last two decades have witnessed the arrival of highly effective second and third-generation azoles and echinocandins. Several new antifungals including nikkomycins, sordaricins, new generation triazoles and echinocandins are also in the pipeline.

Pediatric patients are not just *little adults*. Compared to adults, they display significant differences in host biology, predisposition, epidemiology and presentation of fungal infections, and pharmacokinetics and pharmacodynamics of antifungal agents. Furthermore, neonates and young infants comprise an entirely unique population. Despite the arrival of several effective antifungals, very few clinical trials have evaluated their pharmacology, clinical safety and efficacy in pediatric age groups. Thus, of the 14 antifungal classes, only a handful are approved for pediatric use, largely based on extrapolated pharmacokinetics data from adults. Even these are often under-dosed and incorrectly prescribed by clinicians due to incomplete understanding of antifungal pharmacology in children. This chapter provides succinct details of current understanding and treatment standards of antifungals approved for pediatric use.

POLYENES

Pharmacology, Spectrum and Resistance

Polyenes comprise of amphotericin B deoxycholate and three lipid formulations including amphotericin B lipid complex (ABLC), amphotericin B colloidal dispersion (ABCD) and liposomal amphotericin B (LAMB). Amphotericin B preferentially binds to fungal ergosterol forming *micropores* in the cell membrane. These pores disrupt fungal cell osmotic integrity, causing leakage of intracellular potassium and magnesium, thereby killing the fungal cell. Additional immune-adjuvant actions include oxidation-dependent stimulation of macrophages, immune cell proliferation, and upregulation of IL-1 β , TNF- α , IL-1RA, IL-12, IFN- γ and nitric oxide production. Amphotericin B lipid formulations have significantly better therapeutic index, selective tissue distribution and lower nephrotoxicity.

Amphotericin B

Amphotericin B is a broadspectrum antifungal active against *Absidia* spp., *Aspergillus* spp., *Basidiobolus* spp., *Blastomyces dermatitidis*, *Candida* spp., *Coccidioides immitis*, *Conidiobolus* spp., *Cryptococcus neoformans*, *Histoplasma capsulatum*, mucoraceous fungi, *Paracoccidioides brasiliensis*, *Rhizopus* spp., and

Rhodotorula spp. (Fig. 1). However, some fungi are intrinsically resistant to it including, *Alternaria* spp., *Aspergillus flavus*, *Aspergillus lentulus*, *Aspergillus terreus*, *Candida guilliermondii*, *Candida lipolytica*, *Candida lusitanae*, *Fusarium* spp.; some isolates of *Penicillium marneffe*, *Scedosporium* spp., *Sporothrix schenckii*, and *Trichosporon* spp. Secondary resistance is rarely seen and is induced by mutations in *ERG2*, *ERG3* and *ERG6* genes encoding ergosterol biosynthetic enzymes, thereby depleting fungal cell membrane ergosterol content.

Use in Pediatrics

Amphotericin B is approved for invasive fungal infections like candidiasis and cryptococcal meningitis in neonates and children. The pharmacokinetics of amphotericin B in children are largely similar to that observed in adults, though significant interindividual variability is noted. Mean clearance rates can vary from 0.12 to 0.039 L/hour/kg and the volume of distribution from 0.37 to 4.1 L/kg. It can attain up to 40–90% of plasma levels in the neonatal cerebrospinal fluid (CSF) by virtue of the immature blood-brain barrier. Based on these observation, amphotericin B deoxycholate is recommended in children at a dose of 0.7–1.0 mg/kg/day administered over 2–4 hour, with careful monitoring for toxicity and renal function (Table 1). Infusion-related toxicity is rare in neonates and younger children; as is nephrotoxicity (0–44%) as compared to adults (~53%). Hypokalemia has been observed in some neonates. Neonates clear amphotericin B most rapidly thus protecting them from nephrotoxicity which is further reduced by sodium loading. Neonates are recommended a dose of 1 mg/kg/day, while preterm neonates are administered 0.5 mg/kg/day.

Amphotericin B lipid formulations of amphotericin B are currently approved for pediatric treatment of refractory invasive aspergillosis, invasive candidiasis and mucormycosis. These formulations also show no significant difference in pediatric pharmacokinetics as compared to adults. All trials indicate body weight as the only cofactor influencing volume of distribution and clearance. Lipid formulations cause substantially less nephrotoxicity and infusion-related toxicity in children, especially with LAMB. Recommended doses for children are 3–4 mg/kg/day ABCD, 5 mg/kg/day ABLC and 3 mg/kg/day LAMB. Very few studies have evaluated lipid formulations in neonates. Neonatal invasive candidiasis is treated with 5 mg/kg/day ABLC or 3 mg/kg/day LAMB (Table 1). Lipid formulations do not reach the CSF in neonates.

AZOLES

Pharmacology, Spectrum and Resistance

Azole antifungals inhibit cytochrome P450-dependent, lanosterol 14- α -demethylase (CYP51), critical for ergosterol synthesis. This compromises cell membrane permeability, impairs membrane-associated oxidative enzymes, and leads to intracellular phospholipid accumulation and cell death. Azoles act considerably slower than polyene antifungals and their effect becomes evident only over several generations of fungal multiplication.

Azoles are broadspectrum agents. Fluconazole is active against *Blastomyces dermatitidis*, most *Candida* spp., *Coccidioides immitis*, *Cryptococcus neoformans*, *Histoplasma capsulatum*, *Rhodotorula* spp., and *Saccharomyces* spp. Itraconazole has a wider spectrum of activity than most azoles. It is active against *Aspergillus* spp., *Blastomyces dermatitidis*, *Candida* spp., *Coccidioides immitis*, *Cryptococcus neoformans*, *Epidermophyton* spp., *Histoplasma capsulatum*, *Malassezia furfur*, *Microsporium* spp., *Paracoccidioides brasiliensis*, *Sporothrix schenckii*, *Trichophyton* spp., and several dematiaceous fungi. Posaconazole is active against *Aspergillus* spp., *Blastomyces dermatitidis*, *Candida* spp., *Coccidioides immitis*, *Fonsecaea pedrosoi*, some *Fusarium* spp.,

Figure 1 Antifungal spectrum of agents recommended for children. Darker blocks denote moderate to excellent in vitro activity against corresponding pathogen; lighter blocks denote minimal activity and/or occasional resistance; and empty spaces denote no antifungal action.

Abbreviations: AMB, amphotericin B; FLUC, fluconazole; ITRA, itraconazole; VORI, voriconazole; POSA, posaconazole; ANID, anidulafungin; CASP, caspofungin; MICA, micafungin.

Table 1 Therapeutic doses of antifungal agents recommended for pediatric use

Antifungal	Neonates (0–30 days)	Infants (1 month–2 years)	Children (2–17 years)	Therapeutic drug monitoring
Amphotericin B deoxycholate	0.7–1 mg/kg/day	0.7–1 mg/kg/day	0.7–1 mg/kg/day	Not required
ABL	2.5–5 mg/kg/day	NA	5 mg/kg/day	Not required
ABCD	NA	3–4 mg/kg/day	3–4 mg/kg/day	Not required
LAMB	3–5 mg/kg/day	3–5 mg/kg/day	3–5 mg/kg/day	Not required
Fluconazole	25 mg/kg loading dose; 12 mg/kg/day maintenance dose	12 mg/kg/day	6–12 mg/kg/day	Not clear, as recent Australian data show variable drug level in adults
Itraconazole	NA	NA	2.5–5 mg/kg 12 hourly	Trough > 0.5 mg/L
Posaconazole	NA	NA	200–400 mg 6–12 hourly	Trough > 1 mg/L
Voriconazole	4–6 mg/kg 12 hourly loading dose; 2–3 mg/kg 12 hourly maintenance dose	4–6 mg/kg 12 hourly loading dose; 2–3 mg/kg 12 hourly maintenance dose	7–9 mg/kg IV 12 hourly; 200–400 mg oral 12 hourly	Trough 1.0–5.5 mg/L
Anidulafungin	1.5 mg/kg/day	1.5–3.0 mg/kg/day	1.5–3.0 mg/kg loading dose; 0.75–1.5 mg/kg/day maintenance dose	Not required
Caspofungin	25 mg/m ² /day	50 mg/m ² /day	70 mg/m ² /day loading dose; 50 mg/m ² /day maintenance dose	Not required
Micafungin	10 mg/kg/day	2–4 mg/kg/day	2–4 mg/kg/day	Not required

Abbreviations: ABL, amphotericin B lipid complex; ABCD, amphotericin B colloidal dispersion; LAMB, liposomal amphotericin B.

Histoplasma capsulatum, the dermatophytes and mucoraceous fungi. Voriconazole is effective against *Alternaria* spp., *Aspergillus* spp., *Bipolaris* spp., *Blastomyces dermatitidis*, all *Candida* spp., including fluconazole resistant *C. krusei* and *C. glabrata*, *Coccidioides immitis*, *Cryptococcus neoformans*, *Histoplasma capsulatum*, *Fusarium* spp., *Paracoccidioides brasiliensis*, *Paecilomyces* spp., *Penicillium marneffei*, *Pseudallescheria boydii*, *Saccharomyces cerevisiae*, *Scedosporium* spp., and *Trichosporon beigelii* (Fig. 1).

Despite their broadspectrum activity, some fungi are intrinsically resistant to azoles. *Candida krusei* is intrinsically resistant to fluconazole and itraconazole. Certain *Aspergillus* spp., *Fusarium* spp., *Scedosporium* spp., *Pseudallescheria boydii* and the mucoraceous fungi are intrinsically resistant to fluconazole, itraconazole and voriconazole. *Sporothrix schenckii* is intrinsically resistant to voriconazole and *Trichosporon* spp. to fluconazole. Secondary resistance results from point mutations, gene amplification, and over-induction of the *ERG11* gene encoding synthesis of 14- α -lanosterol demethylase. Over expression of energy-dependent efflux pumps including, the ATP-binding cassette (ABC) super-family proteins and the major facilitator super-family (MFS) proteins, also play a major role in preventing intracellular accumulation and action of azoles.

Azoles either inhibit or are metabolized by cytochrome P450 isoenzymes CYP3A4, CYP2C9 and CYP2C19. Thus any drug which inhibits, induces or utilizes these isoenzymes shows wide interactions with azoles. Itraconazole and voriconazole are particularly notorious. Drugs such as astemizole, cisapride, halofantrine, pimozone, quinidine, terfenadine, ergot alkaloids are contraindicated with azoles because they precipitate toxicity. On the other hand, rifabutin, phenytoin, omeprazole, benzodiazepines and non-nucleoside reverse transcriptase inhibitors (NNRTIs) need to be monitored along with azoles for therapeutic failure. It is also highly desirable that itraconazole, voriconazole and posaconazole should be placed on therapeutic drug monitoring.

Fluconazole

Fluconazole is approved for oropharyngeal, esophageal, and invasive candidiasis in children. Its plasma clearance is significantly more rapid in children yielding a significantly shorter half-life than adults. Drug clearance may be reduced in premature infants during the first few days of life. Population-based pharmacokinetics recommends a dose of 6–12 mg/kg/day in children over 4 weeks of age (Table 1). Severe infections such as invasive candidiasis require a minimum dose of 12 mg/kg/day to achieve an area under the concentration curve (AUC)/minimum inhibitory concentration (MIC) index more than 50. Dose adjustment is recommended in children with serum creatinine more than 1.3 mg/dL, which does not resolve within 96 hour. Fluconazole prophylaxis for early prevention of candidiasis is administered at 3–6 mg/kg twice weekly during first 42 days of life in 23–29 week infants and at 6 mg/kg doses every 72 hour or 3 mg/kg/day for late prevention. Most common side effects in children include gastrointestinal disturbances (8%), elevated hepatic transaminases (5%) and skin reactions (1%). The Infectious Diseases Society of America (IDSA) recommends a loading dose of 25 mg/kg followed by maintenance dose of 12 mg/kg/day in infants and neonates, to rapidly achieve therapeutic levels and an AUC of more than 400 mg hour/L (Table 1).

Itraconazole

Although itraconazole is not approved by the US Food and Drug Administration (FDA) and the European Medicines Agency (EMA) for use in individuals less than 18 years of age, but this has been employed in children for salvage and compassionate therapy. Itraconazole oral solution is given for oropharyngeal

candidiasis at 2.5 mg/kg twice daily (cumulative 3–5 mg/kg/day, up to a maximum of 100 mg) in children more than 5 years of age (Table 1). Itraconazole oral solution is not available in India. The pharmacokinetics of oral tablet is complex, because their gastrointestinal absorption varies with acid content and food intake. Therefore, therapeutic drug monitoring becomes essential while the patient is on itraconazole oral tablets. Cystic fibrosis and allogeneic bone marrow transplant children with invasive fungal infection are prescribed 5 mg/kg twice daily (maximum 200 mg) oral itraconazole with therapeutic drug monitoring and a target trough level of 0.5 μ g/mL. Limited studies of intravenous itraconazole use in children aged 7 months to 17 years indicate a dosing approach based on body weight. The British National Formulary for Children recommends 2.5 mg/kg every 12 hour (maximum 200 mg) for 2 days followed by 2.5 mg/kg once daily for a maximum of 12 days. Common side effects in children include vomiting (12%), abnormal liver function tests (5%), and abdominal pain (3%). Nephrotoxicity becomes an important issue due to the cyclodextrin present in itraconazole intravenous solution. Pharmacokinetics data for neonates are not available.

Posaconazole

Posaconazole is a new generation broadspectrum azole, particularly, important for its activity against mucoraceous fungi. It has not yet been approved for patients less than 18 years of age. Few studies have examined its pharmacokinetics in children receiving salvage therapy at 800 mg/day (Table 1). Though no significant side effects different from adults have been noted, systematic trials are currently underway to elucidate its dosage, safety and efficacy in children more than 4 weeks old.

Voriconazole

Voriconazole is a third-generation, broadspectrum azole. It is approved for treatment of invasive fungal infections in children 2 years or older. Unlike its nonlinear pharmacokinetics in adults, voriconazole exhibits linear pharmacokinetics in children, thereby requiring higher dose in children to attain comparable therapeutic levels as in adults. Children also have lower oral bioavailability than adults (45–65% vs 96%) probably due to greater first-pass metabolism.

For children, 12 years or older intravenous voriconazole is prescribed at 6 mg/kg twice daily on day 1 followed by 4 mg/kg twice daily. Oral voriconazole is administered for the first 24 hour, with a 12 hourly loading dose adjusted by body weight. Children weighing more than 40 kg are given 400 mg, while those weighing less than 40 kg receive 200 mg. Subsequent oral maintenance dose for those weighing more than 40 kg is 200 mg twice daily, raised to 300 mg twice daily in case of inadequate response. Children weighing less than 40 kg receive 100 mg twice daily increased to 150 mg twice daily in case of inadequate response. Children aged 2–11 years eliminate voriconazole significantly faster than adults. This is mediated by faster CYP2C19 cytochrome metabolism and flavin-containing monooxygenase-3 activity. Hence, children aged 2–11 years are recommended 200 mg twice daily oral and 7–9 mg/kg twice daily intravenous voriconazole, with no loading dose over first 24 hour. If the child is unable to tolerate high dose therapy, the dose should be brought down to 4 mg/kg twice daily (Table 1). Intravenous voriconazole should be infused at a maximum rate of 3 mg/kg/hour over 1–2 hour. Pharmacokinetic data is sparse for neonates and children less than 2 years of age. The FDA has not allowed any study in children less than 24 months given the deleterious effects of voriconazole on the developing retina. Limited studies recommend a 4–6 mg/kg 12 hourly loading dose followed by 2–3 mg/kg 12 hourly in neonates and preterm infants, although doses as high as 9 mg/kg 12 hourly have also been

administered to maintain adequate trough levels. Therapeutic drug monitoring is recommended.

Common adverse effects in children include elevated hepatic transaminases, vision abnormalities, skin rash and photosensitivity. Its use in small children involves the concern of long-term adverse effects on the developing retina. Long-term administration in immunosuppressed patients is possibly linked to aggressive squamous cell carcinoma and should be guarded against during prolonged therapy in children.

ECHINOCANDINS

Pharmacology, Spectrum and Resistance

Echinocandins are semi-synthetic glycopeptides that inhibit the production of 1,3- β -glucan, a critical fibrillar fungal cell wall component. This compromises fungal cell wall integrity thereby disrupting its shape, ion and small molecule exchange, surface presentation of molecules and the cell's internal milieu. Echinocandin action is rapid, noncompetitive and most prominent at growing hyphal tips and budding sites. It eventually kills the fungal cell by osmotic lysis. Echinocandins are fungicidal toward most yeasts and fungistatic towards filamentous fungi.

Echinocandins are active against most *Aspergillus* spp., *Candida* spp. including those resistant to azoles and *Saccharomyces cerevisiae*. However, *Candida parapsilosis*, *Candida guilliermondii*, and *Candida famata* require higher minimum inhibitory concentrations than other *Candida* spp. Echinocandins are also effective against mycelial (and not yeast) forms of *Histoplasma capsulatum*, *Blastomyces dermatitidis*, *Coccidioides immitis* (Fig. 1). They show variable efficacy against dematiaceous fungi and *Pneumocystis jirovecii* and only minimal activity against *Fusarium* spp., *Pseudallescheria boydii*. Echinocandins are particularly effective against amphotericin B and fluconazole resistant *Candida* and *Aspergillus* isolates. Echinocandins target glucan synthase encoded by the *FKS1*, *FKS2* and *RHO1* genes, essential for 1,3- β -glucan synthesis. *Cryptococcus neoformans*, *Fusarium* spp., *Scedosporium* spp., *Trichosporon asahii* and the mucoraceous fungi are intrinsically resistant to echinocandins, because they do not synthesize 1,3- β -glucan for their cell wall. Secondary resistance is conferred by *FKS1* and *FKS2* point mutations and substitutions which alter glucan synthase activity.

Anidulafungin

Anidulafungin demonstrates linear pharmacokinetics and longest half-life among echinocandins. Advanced safety and efficacy trials in children aged 2–11 years and 12–17 years reveal pharmacokinetics similar to adults with no serious adverse effects. These studies recommend a weight-adjusted regime with 1.5–3.0 mg/kg loading dose followed by 0.75–1.5 mg/kg/day maintenance dose for children aged 2–17 years (Table 1). A 1.5 mg/kg/day dose produces comparable therapeutic levels in infants and neonates. Despite these studies, anidulafungin has not been approved for use in children by the FDA and EMEA, given the lack of sufficient clinical experience.

Caspofungin

Caspofungin is licensed by the EMEA and FDA (2008) for use in children and neonates suffering from invasive aspergillosis, invasive candidiasis and for empiric therapy in febrile neutropenic patients. Studies in children aged 2–17 years showed that a weight-adjusted dose of 1 mg/kg/day offered suboptimal exposure. Body surface-area adjusted dosing at 50 mg/m²/day yielded therapeutic levels comparable to adults. Further population pharmacokinetic studies confirmed these findings and also recommended a dose of 25 mg/m²/day for neonates and infants up to 3 months of age

(Table 1). Combined analysis of five pediatric trials show good tolerance in children. Common adverse effects including fever (11.7%), elevated transaminases (6.5%), skin rash (4.7%) and therapeutic success rates are similar to adults.

Micafungin

Micafungin is approved by the EMEA (2008) and FDA (2013) for treatment and prophylaxis of invasive candidiasis in pediatric patients with febrile neutropenia and allogeneic stem cell transplant. It is administered at 100 mg/day or 2 mg/kg/day, if the child weighs less than 40 kg. The dose may be raised to 200 mg/day or 4 mg/kg/day in cases of invasive candidiasis. Esophageal candidiasis is treated with 150 mg/day (3 mg/kg/day for ≤ 40 kg), and prophylaxis is administered at 50 mg/day (1 mg/kg/day for ≤ 40 kg) (Table 1). Multicenter trials in children aged 2–17 years indicate no dose-limiting toxicities, linear pharmacokinetics similar to adults, and no variations in drug clearance, distribution volume and drug half-life on repeated dosing. Combined analysis of six pediatric trials revealed adverse events in 26.7% children, but no different from adults. Micafungin clearance is significantly faster in neonates and premature infants than that predicted by body weight alone. Trial data and pharmacokinetic modeling suggest higher doses for extremely low birth weight neonates (15 mg/kg/day), low birth weight neonates (7 mg/kg/day) and normal neonates (4 mg/kg/day). A higher 10 mg/kg/day dose is recommended for neonatal central nervous system fungal infections. The appropriate dose of micafungin for neonates is still under debate. Based on animal studies showing liver tumorigenesis, the EMEA advises careful monitoring of liver function and early discontinuation of micafungin with increasing hepatic transaminases.

FLUORINATED PYRIMIDINES

Pharmacology, Spectrum and Resistance

Flucytosine is a low molecular weight, water-soluble, fluorinated pyrimidine analog which inhibits fungal RNA and DNA synthesis. It is internalized by fungus-specific cytosine permease and activated by fungal cytosine deaminase to the antimetabolite, 5-fluorouracil (5-FC). 5-FC competitively replaces uracil in fungal RNA, causing RNA miscoding and disrupting protein synthesis. It also inhibits *thymidylate synthase* thereby inhibiting fungal DNA synthesis.

Flucytosine is active against most *Candida* spp., *Cryptococcus neoformans*, *Cladosporium* spp., *Fonsecaea* spp., *Phialophora* spp., and *Saccharomyces* spp. Intrinsic resistance is seen in some strains of *Candida albicans*, *Candida krusei*, *Cryptococcus neoformans* and *Aspergillus* spp., and is conferred by mutations altering cytosine deaminase activity. Most zygomycetes and dermatophytes are intrinsically resistant to flucytosine. Secondary resistance is frequently acquired during treatment, especially when flucytosine is used for monotherapy. Point mutations in the *FCY1* and *FCY2* genes encoding for purine-cytosine permease and cytosine deaminase, respectively, are commonly responsible for secondary resistance.

Use in Pediatrics

Although systematic flucytosine pharmacokinetic data for children is unavailable, limited studies indicate high interindividual variability in clearance rates and distribution volumes in neonates. Currently, recommended doses in children are similar to that in adults at 100 mg/kg/day in 3–4 divided doses. Accumulation of flucytosine due to immature pediatric renal function can lead to marrow toxicity and therapeutic drug monitoring is advised to maintain plasma levels between 40–60 μ g/mL. Flucytosine is recommended in combination with amphotericin B especially for cryptococcal meningitis.

IN A NUTSHELL

1. Each antifungal has its pharmacokinetic peculiarities in children and cannot be prescribed simply at weight-adjusted doses.
2. Despite their immature renal function, small children and neonates clear antifungals much more rapidly than adults.
3. Amphotericin B deoxycholate induced infusion-toxicity and nephrotoxicity are less in neonates and small children.
4. Fluconazole is rapidly cleared by infants and neonates requiring a higher loading dose.
5. Itraconazole is prescribed at weight-adjusted doses, but therapeutic monitoring is recommended, given its unpredictable absorption.
6. Voriconazole demonstrates linear pharmacokinetics, higher first-pass metabolism and lower bioavailability in children thus requiring higher doses. Voriconazole may be avoided in neonates due to possible toxicity during retinal development.
7. Therapeutic drug monitoring is recommended for itraconazole, posaconazole, voriconazole and may also be monitored for fluconazole.
8. Caspofungin is administered at doses adjusted for body surface-area, since weight-adjusted doses pose a high risk of therapeutic failure.
9. Despite its linear pharmacokinetics, micafungin is cleared much faster by neonates and infants. Clearance cannot be predicted by body weight alone and higher doses are recommended.
10. It is recommended to prescribe flucytosine in combination with amphotericin B to prevent drug resistance.

Chapter 33.3

Candidiasis

Kheya Ghosh Uttam

Candidiasis is the most common fungal disease found in humans. *Candida* is also the fourth most common organism recovered from blood cultures in hospitalized patients. In India, there are only few diagnostic mycotic laboratories and centers which carry routine medical autopsies. Thus, there is limited data regarding exact frequency of mycotic infections. However, India being a tropical country getting heavy rainfall, having few millions HIV-infected population, less than optimal infection control practices and rampant use of systemic steroids, certainly has a high prevalence of opportunistic mycoses. Recent data suggest that invasive candidiasis is the most common invasive mycotic infection across India. Incidence varies from 1–12 per 1,000 admissions in different hospitals across the country. Neonatal ICUs, pediatric ICUs and surgical ICUs report high incidence of candidemia. Candidiasis may be superficial or systemic (invasive) and with wide clinical presentations.

EPIDEMIOLOGY

Candida is a small (4–6 µm) oval-shaped yeast. *Candida* species are the component of normal flora of human beings and reproduce by budding. Alteration of balance between the host resistance and the normal microbial flora predispose to candidiasis.

Agent Of 163 species of the genus *Candida*, 20 are considered significant. The most common pathogenic species is *Candida albicans*. Over the past two decades, there is significant increase of non-*albicans* *Candida* species including *Candida tropicalis*, *Candida krusei*, *Candida glabrata* and *Candida parapsilosis*. In India, non-*albicans* *Candida* species are identified in 30–90% cases of invasive candidiasis. *C. tropicalis* is the most common species among non-*albicans*. Resistance to fluconazole is seen in less than 10% strains of *C. tropicalis*.

Risk factors Most studies in India identify prolonged hospitalization, central venous access, total parenteral nutrition, use of broadspectrum antibiotics for long duration, mechanical ventilation, major abdominal surgery and immunosuppression (corticosteroid or other immunosuppressive therapy, neutropenic patients, children with endocrine disorders, HIV, burn and malignancy and neonates) as risk factors for candidemia.

PATHOGENESIS

Candida species has several properties responsible for its pathogenicity in immunocompromised states. These include adherence to epithelial and endothelial cells, proteinase production, pseudohyphae formation, phenotypic switching, phospholipase production and antigenic modulation due to pseudohyphae formation.

Candida normally inhabits the gastrointestinal tract, the female genital tract and the skin. The portal of entry is usually mucosal or skin. Intact epithelial barriers, normal neutrophils, lymphocyte and macrophage function, adequate antibody and complement level, and normal bacterial flora are the host factors which prevent invasion. During penetration of skin or mucous membrane, the yeast cells of *Candida* are transformed into hyphal form. Hyphae being larger than the yeast are more resistant to phagocytosis. It is believed that high concentration of phospholipase enzyme at the tip of the hyphae may be related to the greater invasiveness of

this form. The phagocytic cells, neutrophils and monocytes, are the most important defensive guard against this invasion. They develop candidacidal activity following fungal penetration, which involve myeloperoxidase and superoxide or cationic proteins. The phagocytic cell activity is crucial for protection against invasive candidiasis. Thus, increased incidence of invasive candidiasis is seen in neutropenic patients. *C. glabrata* can cause invasive candidiasis even though it does not transform into pseudohyphal or hyphal form.

CLINICAL FEATURES

Candidiasis can affect different organ systems and the spectrum varies from benign superficial infections to deep invasive or systemic infections.

Superficial Candidiasis

Oral thrush Oral thrush is common in normal infants in the first week of life. Thrush in older children is unusual unless they have recently received antimicrobials or are immunosuppressed. In older children, corticosteroid inhalation for treatment of bronchial asthma is the most common predisposing factor. Typically, the lesions are few or extensive, adherent creamy white, discrete or confluent plaques on the buccal, gingival, palatal or lingual mucosa. Oral thrush may be asymptomatic or it may cause pain and decreased feeding (**Figs 1 and 2**).

Angular cheilitis Angular cheilitis is caused by *Candida* at the corners of the mouth, often in association with a vitamin B₁₂ or iron deficiency. The patient presents with sore, erythematous fissured lesions affecting the angles of the mouth and may be associated with denture stomatitis. A significant number of patients with HIV have angular cheilitis (**Fig. 3**).

Diaper dermatitis Maceration and wet diapers predispose infants to diaper dermatitis. An erythematous maculopapular rash in the perineum, inguinal fold and intertriginous areas is commonly seen initially. The lesions coalesce and become confluent with satellite pustules. Pustules, vesicles and scales may be seen. Moist areas, such as axilla or neck folds may also be involved. The precipitating factors for *Candida* infection include are mechanical friction, prolonged contact with urine and feces, application of topical ointment and alteration of skin pH.

Congenital cutaneous candidiasis These lesions may be seen in babies born to a mother with *Candida* amnionitis or after prolonged rupture of membranes in an infected mother. A red

Figure 1 Oral thrush in a neonate

Figure 2 Oral thrush in older child

Figure 3 Angular cheilitis

maculopapular or pustular rash or erythema is characteristically present at birth.

Vaginal infection Vulvovaginitis due to candida occurs in young girls, middle aged and pregnant women, diabetic patients, and in those on prolonged antibiotic or oral contraceptive therapy. Patients present with thick, odorless, curdy or cheesy discharge with intense pruritus or burning sensation and dyspareunia. The vagina and labia may be erythematous and edematous.

Balanitis and balanoposthitis Balanitis and balanoposthitis are found primarily in uncircumcised adolescent boys. The lesions are whitish, pustular associated with erythema and pruritus, and found over glans. Sometimes edema and erosion of prepuce leads to acquired phimosis. As similar lesions may be produced by other conditions, laboratory support should be sought for the diagnosis of genital candidiasis.

Paronychia and onychomycosis Paronychia is an inflammation of the nail fold primarily affecting the finger nails and may

involve the toe nails. These conditions may occur in immunocompetent children but are more commonly associated with immunosuppression, diabetes mellitus, hypoparathyroidism, or adrenal insufficiency (*Candida* endocrinopathy syndrome). Paronychia and onychomycosis is usually caused by *Trichophyton* and *epidermophyton* but can also be due to *Candida* species, which usually involves the fingernails.

Intertrigo Intertrigo is an erythematous inflammation of the skin folds. These red pustular lesions often develop superimposed bacterial infections. When secondarily infected, may develop lymphangitis and lymphadenopathy. It occurs predominantly in adolescent females.

Chronic mucocutaneous candidiasis Chronic mucocutaneous candidiasis refers to infection at multiple sites in skin, mucous membrane, nails and hair which persists despite antifungal therapy. The disease usually starts in infancy or within the first two decades of life. The lesions are hyperplastic and nodular. These may be mild and limited to an area or may be severe characterized by exophytic growths on skin. Despite severe cutaneous involvement, they rarely develop invasive candidiasis. Underlying pathology includes defective cell mediated immunity where the T lymphocytes fail to proliferate or to stimulate cytokines in response to *Candida* antigen. Invasive candidiasis is rare because the function of neutrophil remains intact. Chronic mucocutaneous candidiasis is associated with many underlying conditions including endocrinopathies, HIV infection, DiGeorge syndrome and hyper IgE syndrome. Almost half of the patients of this group has autoimmune polyendocrinopathy-candidiasis-ectodermal dystrophy (APECED) syndrome. The lesions are followed by onset of hypoparathyroidism, adrenal insufficiency, autoimmune thyroiditis, Grave's disease, chronic active hepatitis, alopecia, pernicious anemia, primary hypogonadism, dental enamel dysplasia, vitiligo, and pitted nail dystrophy.

Keratoconjunctivitis Candidal keratoconjunctivitis presents with conjunctival edema, cheesy discharge and progressive corneal ulceration. This occurs following long-term use of topical corticosteroids.

Deep invasive candidiasis Deep invasive candidiasis usually results from hematogenous spread. But it may result from contiguous spread from skin as in superficial erosions, deep wounds, catheter related or from alimentary tract to other abdominal organs during perforation of GI tract.

Gastrointestinal candidiasis Candidiasis may involve esophagus and rarely stomach, in immunosuppressed children. Esophagitis may be asymptomatic or it may cause burning sensation in throat and suprasternal area of chest, dysphagia, and anorexia. Upper GI endoscopy reveals white plaques on the mucosal surface, notably in the distal third of esophagus. Nausea and vomiting are common in young children. Many may not have associated oral thrush. Stomach or intestinal ulcers may occur. Atrophic glossitis, chronic hyperplastic candidiasis may occur in critically ill children. A syndrome of mild diarrhea occurs in normal individuals. *Candida* is not considered as a true enteric pathogen, its presence mostly in stool likely reflects recent antimicrobial therapy. Retrograde migration from GI tract into biliary tract may cause gallbladder infection.

Pulmonary infection *Candida* is commonly isolated from respiratory secretions as it frequently colonizes the respiratory tract. Mere isolation of *Candida* species from respiratory tract does not imply invasive pulmonary infection. Demonstration of tissue invasion is essential to diagnose *Candida* pneumonia or tracheitis. It is a rare condition seen in immunosuppressed children and in those intubated for long periods, and on broadspectrum antibiotics. The pulmonary infection may cause fever, cough, abscesses, reticulonodular infiltrates, and effusion.

Urinary tract infection Candiduria may reflect colonization or may be the only manifestation of urinary tract disease. Most of the patients are asymptomatic. More often, candiduria is associated with instrumentation, *in situ* catheter, abnormality of the urinary tract or immunosuppressed host especially in diabetics. Rarely, masses of *Candida* (fungal balls) may obstruct ureters and cause obstructive nephropathy. *Candida* casts in the urine suggest renal tissue infection.

Other infections Any organ in human body can be infected by *Candida*. Once *Candida* enters intravascular compartment, dissemination may occur in any of the deep organs especially in immunocompromised patients and neonates. Endocarditis, myocarditis, meningitis, and chorioretinitis are common while liver, spleen bone and joints are less commonly involved. Hepatosplenomegaly may occur in immunosuppressed, severely neutropenic patients with chronic fever, variable abdominal pain, and abnormal liver function tests. It may occur with or without fungemia. *Candida* endophthalmitis is characterized by one or more focal white lesions in the retina associated with haziness of the overlying vitreous. Presence of chorioretinitis indicates high probability of formation of abscess in deep multiple organs. Thus, an ocular examination is a must in all children with candidemia. Rarely endocrine glands, pancreas and skeletal muscles may get involved. If there is persistent candidemia, then the occult organ involvement should be considered.

Disseminated candidiasis This occurs in neonates, especially in premature infants, in an intensive care setting, and should be suspected when the baby fails to respond to adequate dose of antibiotics. These infants have unexplained feeding intolerance, cardiovascular instability, apnea, new or worsening respiratory problems, fluctuating glucose levels, thrombocytopenia, or hyperbilirubinemia. Disseminated candidiasis is also common in children with hematological malignancies, and in those undergoing bone marrow or organ transplantation. Treatment for presumptive infection is often undertaken because candidemia is not identified in many such patients.

LABORATORY DIAGNOSIS

The greatest challenge to diagnose *Candida* infection is to differentiate an isolate as mere colonization or as infection. The other diagnostic difficulty is absence of a sensitive serological test.

Direct Examination

Skin or nail scrapings, sputum, swab from patches in the mouth, throat or vagina are examined in KOH, wet mount preparation for visualization of yeast cells, pseudohyphae or hyphae. Gram staining is performed to see all these forms of the fungus. Absence of organisms on hematoxylin-eosin stained specimen does not exclude the diagnosis. Calcofluor white stain may be used to highlight the fungal elements. Demonstration of pseudohyphae is highly significant as it indicates tissue invasion.

Fungal Culture

Isolation of *Candida* species in blood culture is the most important diagnostic tool for fungal infection. The yield of old blood culture technique was very low. The clinical specimens are cultured with antibacterial antibiotics and incubated at 25°C and 37°C. Different species can be identified by their colony characteristics (**Figs 4A and B**), biochemical tests such as sugar fermentation and assimilation reactions.

Serological Tests

Despite extensive efforts, there is no current antigen or antibody detection test available which has good sensitivity and specificity. A positive antibody detection test does not necessarily indicate infection as it is unable to differentiate antibodies formed by colonization or by deep infection. Negative antibody test also does not rule out infection as immunocompromised patients may not be able to mount adequate antibody response. Antigen detection is likely to emerge as an important method of serodiagnosis in coming years. Detection of cell wall component such as cell wall mannoprotein (CWMP) β -(1,3)-D- glucan are undergoing several studies to establish their utility.

TREATMENT

Superficial Candidiasis

Topical nystatin is used for oral and mucocutaneous candidiasis. Topical azoles are used and are preferable mode of treatment. Vulvovaginal candidiasis is treated with azole or nystatin suppository and may require oral fluconazole.

Invasive Candidiasis

As there is no reliable way to distinguish between benign candidemia or colonization and deep invasive candidiasis, all children with candidemia should be treated with antifungal drugs. In addition, the

Figures 4A and B (A) *Candida albicans* in corn meal agar; (B) *Candida glabrata* in corn meal agar

indwelling catheter, infected valve or prosthesis should be removed. Selection of the initial antifungal depends upon previous use of azole either as prophylaxis or therapy, severity of the disease, organ involvement, immune status of the patient, common isolates of that unit and their sensitivity pattern. Once the species is identified and antifungal susceptibility report is available the treatment is altered accordingly. Presently, majority of *C. albicans* are sensitive to fluconazole. *C. glabrata* and *C. krusei* are less sensitive to fluconazole and more sensitive to polyenes and echinocandins.

The drugs used for the treatment of candidiasis with their doses are shown in **Table 1**. Polyenes (amphotericin B and its lipid preparation), azoles and echinocandins are available treatment options. No agent has been clearly identified superior to other. However, amphotericin B or echinocandins are preferably used as first line drug in severely ill or unstable patients with candidemia in certain centers.

In patients with meningitis, the recommended treatment is intravenous polyenes plus flucytosine. Renal function should be monitored closely in patients who receive amphotericin B. Removal of infected prosthetic valve and prolonged antifungal therapy is required for *Candida* endocarditis. *Candida* endophthalmitis often require partial vitrectomy in addition to treatment with IV polyenes and flucytosine. Candiduria in a hospitalized patient with or without a catheter may represent colonization. However, systemic antifungal treatment with fluconazole should be started in seriously ill patients, in immunocompromised, in patients with obstructive renal diseases and in preterm low birth weight babies. Antifungal therapy should be continued for 2 weeks after the last positive blood culture.

Table 1 Recommended antifungals for treatment of invasive candidiasis in children

Drugs	Dose and route	Comment
Amphotericin B deoxycholate	1–1.5 mg/kg/day, IV	Broadspectrum, nephrotoxic
Liposomal amphotericin B	3–5 mg/kg/day, IV	Broadspectrum
Fluconazole	6–12 mg/kg/day, IV and oral	Most commonly used
Voriconazole	6–8 mg/kg/day, IV and oral	Multiple drug interaction
Caspofungin	50 mg/m ² /day, IV	Broad spectrum

PROPHYLAXIS

Prophylaxis treatment with antifungal agent is controversial. It should not be encouraged as there will be increased resistance to common antifungals. Increase incidence of *non-albicans candida* species is also a concern following prophylactic use of antifungal drugs. Prophylactic fluconazole is recommended for patients undergoing bone marrow or organ transplant. Till now, there is no consensus for use of antifungal prophylaxis in neutropenic patients.

IN A NUTSHELL

1. Candidiasis is the most common fungal disease found in human.
2. In India, incidence of invasive candidiasis varies from 1–12/1,000 hospital admission.
3. Though the most common pathogenic species is *Candida albicans*, there is significant increase of non-albicans *Candida* in the past two decades.
4. Presumptive antifungal treatment should be given to a child with risk factor who fails to improve after adequate dose of antibiotic.
5. Prophylaxis antifungal treatment should be strongly discouraged, except in bone marrow and organ transplant patients.

Chapter 33.4

Aspergillosis

Kana Ram Jat

Aspergilli, the ubiquitous fungi, have about 185 species with *Aspergillus fumigatus* (AF), *Aspergillus niger*, and *Aspergillus flavus* being most common that cause diseases in human. Human are exposed to spore such as conidia of *Aspergillus*, which float in air, almost daily. Usually, inhaled airborne conidia are cleared by macrophage and neutrophil-mediated phagocytosis in normal people and rarely cause disease. Aspergilli cause disease in immunosuppressed person, in genetically susceptible person or after inhalation of very high doses of conidia.

Aspergillus may cause three separate groups of diseases: (1) Hypersensitivity (e.g., allergic bronchopulmonary aspergillosis (ABPA); *Aspergillus* mediated asthma and hypersensitivity pneumonia; and malt worker's disease), (2) saprophytic (non-invasive e.g., aspergilloma) and (3) invasive disease [e.g., invasive aspergillosis (IA)] depending on host's immune status and quantity and virulence of inhaled *Aspergillus*. Of these, ABPA is an important and common disease caused by *Aspergillus* species. *Aspergillus mediated asthma* refers to an exacerbation of known asthma following inhalation of *Aspergillus* spores. It is a Th2 hypersensitivity lung disease caused by sensitization to *Aspergillus* antigens that occur mainly in people with cystic fibrosis or asthma. *Hypersensitivity pneumonitis* is an extrinsic alveolar alveolitis caused by repetitive inhalation of *Aspergillus* conidia and manifest as cough, fever, and breathlessness. Eosinophilia is absent in blood and sputum.

ALLERGIC BRONCHOPULMONARY ASPERGILLOSIS

Epidemiology

Aspergillus fumigatus is responsible for majority of ABPA cases. Overall, these occur in about 1–2% of children with asthma and 2–15% of patients with cystic fibrosis (CF). One study from India showed unusually high prevalence of ABPA where 15% of children with perennial asthma and 6.5% of total asthmatic children screened were found to have ABPA. A recent study from Delhi revealed 18.2% prevalence of ABPA in children with CF. Though sensitization to *Aspergillus* is common in asthmatic and CF patients (20–25% of asthmatic patients and 31–59% of CF patients), only a small percentage of these patients develop ABPA. Low body mass index, low CF score, age more than 12, atopy, eosinophilia, colonization with other fungi are some of the risk factors for developing ABPA in CF patients.

Pathophysiology

Inhaled *A. fumigatus* spores germinate into hyphae within bronchi and release various proteins (e.g., proteases, superoxide dismutases, hemolysin, etc.) and toxins which induce production of inflammatory cytokines and chemokines, such as IL-6, IL-8 that leads to disruption of pulmonary epithelium and persistent abnormal immunological inflammatory response. People with asthma and CF that develop ABPA are found to have some genetic susceptibility factors. Lack of HLA-DQ2 and presence of HLA-DR2 and/or DR5 had increased risk of ABPA when exposed to *Aspergillus*, whereas presence of HLA-DQ2 (especially HLA-DQB1*0201) is supposed to have protective effect against ABPA. Polymorphism of IL-4 receptor α chain and 1082GG genotype of the IL-10 promoter may also have a role in pathogenesis of ABPA in cystic fibrosis.

Clinical Features

Allergic bronchopulmonary aspergillosis results in exacerbation of asthma or CF with lung infiltrates on chest X-ray along with sputum and blood eosinophilia. The ABPA presents with worsening cough and wheezing which may be accompanied by fever, malaise, and expectoration of brown plugs. The ABPA may be in chronic form with intermittent acute exacerbations. Chest examination may reveal findings of underlying disease, i.e., asthma or CF along with wheeze and/or crepitations. A child with associated bronchiectasis may have clubbing, weight loss, and coarse crepitations. The ABPA should be suspected in asthmatics that are difficult to control or inadequately treated with marked eosinophilia. Children with CF who show wheezing, pulmonary infiltrates and reduced lung function despite adequate treatment for CF should be investigated for ABPA. Clinical staging of ABPA (Patterson staging) is tabulated in **Box 1**.

Radiology Findings

Central bronchiectasis (**Fig. 1**) and fleeting shadows are the most common radiological findings in ABPA both in children and adults. The other findings are large homogeneous shadow (patchy, lobar or triangular) mostly in upper lobe without volume loss, *tram line appearance* (fine parallel lines from hila due to inflamed airways), toothpaste shadows, gloved-finger shadows due to mucus impaction, dilated and totally occluded bronchi, bronchial wall thickening, and ring shadows. High resolution computerized tomography (HRCT) is the investigation of choice to delineate lung lesions in ABPA.

Box 1 Clinical stages for allergic bronchopulmonary aspergillosis (ABPA)

Stage I:	Acute exacerbation of disease with most of the classical features
Stage II:	Remission
Stage III:	Recurrence of exacerbation with two times increase in IgE levels
Stage IV:	Where patients need continuous steroids to control the disease
Stage V:	Fibrotic stage which responds poorly to steroids and may lead to pulmonary hypertension and cor pulmonale

Figure 1 An asthmatic child with allergic bronchopulmonary aspergillosis (ABPA) showing central bronchiectasis

Diagnosis

The diagnostic criteria for ABPA in asthma and cystic fibrosis are same for adults and children. Rosenberg-Patterson criteria in 1977 included following eight characteristics: (1) asthma or cystic fibrosis; (2) peripheral blood eosinophilia ($> 1.0 \times 10^9/L$); (3) immediate cutaneous reactivity to AF antigen; (4) precipitating antibodies against AF antigen; (5) elevated total serum IgE ($> 1,000$ ng/mL); (6) Chest X-ray infiltrates (or history of), transient or fixed; (7) proximal bronchiectasis; and (8) elevated serum IgE and IgG antibodies (specific to AF antigen). Two years later, Nelson, et al in 1979 suggested at least five of the following seven criteria for diagnosing ABPA in CF patients, viz. wheezing, increased total serum IgE, positive specific IgE to *A. fumigatus*, serum *Aspergillus* IgG precipitins, positive skin test, radiological pulmonary infiltrates, and bronchiectasis. The recent criteria for diagnosis of ABPA in asthmatic patients as proposed by Greenberger is shown in **Table 1**. Recently, Cystic Fibrosis Foundation consensus had laid down diagnostic criteria of ABPA in cystic fibrosis as well as criteria for screening for ABPA in cystic fibrosis patients (**Table 2**). Diagnosis of ABPA in CF patients may be difficult as many clinical features, e.g., airway obstruction, pulmonary infiltrates, and bronchiectasis may be present in them even without ABPA.

Presence of *A. fumigatus* in sputum culture is nonspecific because patients with CF and even normal subjects without ABPA may harbor *Aspergillus*. IgE level is a useful disease activity marker and may be used in monitoring. Skin prick test is an important screening test for ABPA as it is uncommon in subjects

with negative result. Serum precipitins are neither sensitive nor specific. Recently, 22 recombinant *A. fumigatus* allergens (named from rAsp f1 to rAsp f22) have been identified and many of them may be useful for discriminating patients with *Aspergillus* sensitization from ABPA. Preliminary studies suggested that rAsp f2, f4, f6, and f16 may be specific for ABPA whereas rAsp f1 and f3 are nonspecific but it needs further research. Other serological markers, e.g., thymus and activation-regulated chemokine (TARC) and exhaled nitric oxide (NO) levels were also used to differentiate ABPA exacerbation from a bacterial exacerbation in CF patients.

Differential diagnosis includes uncontrolled asthma, foreign body inhalation, pneumonia, tuberculosis, immotile cilia syndrome, pulmonary infiltrates with eosinophilia, CF without ABPA, and sarcoidosis.

Management

Management of ABPA includes use of steroids for control of inflammation; and itraconazole to suppress *Aspergillus* colonization. Systemic corticosteroids are mainstay treatment for ABPA. Treatment is started with 0.5 mg/kg/day of oral prednisolone for 2–4 weeks with monitoring for clinical improvement and radiological clearance. After improvement from acute process, prednisolone (0.5 mg/kg) is given on alternate days for next 1–3 months and then tapered off over next 3 months while checking clinically and with serum IgE levels. Steroid dose is needed to increase, if IgE levels increases two folds or more. There is lack of evidence for or against the use of inhaled steroids and pulse methylprednisolone.

Itraconazole decreases the fungal burden and reduces inflammatory stimulus. Itraconazole is supposed to reduce the doses of steroids that are required along with decreased episodes of acute exacerbation in ABPA. Randomized controlled trials (RCTs) in asthmatic adults with ABPA suggest beneficial effect of itraconazole. There are no RCTs in CF patients with ABPA for use of itraconazole. Itraconazole is proposed for ABPA in CF patients based on observational studies. In children, usual dose of itraconazole is 10 mg/kg/day in two divided doses (maximum dose 400 mg/day). The total duration of therapy should be 3–6 months. Several other antifungal drugs (e.g., amphotericin B, ketoconazole, clotrimazole, nystatin and natamycin) have also been used for treatment of ABPA, but had adverse effects.

Anti-IgE therapy (omalizumab) is effective for allergic asthma but there is lack of evidence for efficacy in ABPA and further research is needed. Immunotherapy for ABPA in children is ineffective and may be risky and therefore, not recommended. Seasonal variation in ABPA may suggest beneficial effects of avoiding places with high burden of *Aspergillus* spores such as compost heaps and damp basements.

Prognosis

Early diagnosis before irreversible lung damage and prompt treatment ensure good prognosis. Prognosis of ABPA in CF patients also depends on progression of CF disease activity. Monitoring of radiological findings and IgE levels are important as clinical features are not so reliable for ABPA progression or remission.

PULMONARY ASPERGILLOMA

Pulmonary aspergillomas (commonly called fungal balls) are mass lesions of fungal hyphae proliferating without vascular invasion. They usually develop in pre-existing cavitory lesions, e.g., tuberculosis, abscesses, lung cysts, and histoplasmosis. Patients may develop fever, cough, and hemoptysis or may be asymptomatic and aspergillomas may be detected as incidental findings on chest imaging. Diagnosis is suggested by positive *Aspergillus* serology. Surgical removal is usual treatment with antifungals in certain subjects.

INVASIVE ASPERGILLOSIS

Invasive aspergillosis is caused by inhalation of conidia that proliferate into fungal hyphae and invade pulmonary vessels and tissue parenchyma. In majority of cases, *A. fumigatus* is responsible for IA. It occurs primarily in immunocompromised patients. Neutropenia, steroids therapy, cytotoxic chemotherapy, chronic granulomatous disease, transplantations, use of broadspectrum antibiotics and leukemia are important predisposing factors for IA. Lung is the most common primary focus, but hematogenous spread may occur to other organ systems. Incidence and prevalence of IA is not well studied in children.

Clinical Features

Patients with pulmonary IA present with fever, cough, and hemoptysis that persist despite use of broadspectrum antibiotics. Symptoms may vary because of underlying immune-deficient state and high index of suspicion is required for diagnosis. Radiological findings are nonspecific and may reveal characteristic *halo sign* (opaque rim around a nodule), *air crescent sign*, nodules, diffuse or lobar consolidation, hemorrhagic infarction and lung abscess.

Diagnosis

Diagnosis of IA is by biopsy and culture; but it may not be feasible to obtain tissue for diagnosis. Tissue-invasive hyphal forms in biopsy and positive culture are confirmatory of IA. Blood culture

and serum studies (because of poor immunological response secondary to underlying immunodeficiency) are not of much use. Bronchoalveolar lavage (BAL) may be of use and polymerase chain reaction (PCR) can further increase the yield. Galactomannan (a cell wall component of *Aspergillus*) based tests have some promise, though it may give false positive results in children receiving piperacillin/tazobactam. Detection of *Aspergillus* in pulmonary secretions (by staining or culture) along with clinical and radiological features is sufficient evidence for IA.

Treatment

Voriconazole is first line therapy for IA. Posaconazole, another azole antifungal, is an alternative drug. Amphotericin, either conventional or liposomal, are considered second line therapy now. Caspofungin is a newer antifungal agent having efficacy against IA. There is a lack of evidence to suggest usefulness of a combination of antifungal drugs for IA. Empirical antifungal therapy may be considered in certain high-risk group when IA is suspected clinically. Reconstitution of immune system by temporary stopping immunosuppressive agents and/or adding colony-stimulating factors is an adjuvant therapeutic modality.

IN A NUTSHELL

1. *Aspergillus* may cause hypersensitivity, saprophytic, or invasive disease in human.
2. Disease pattern of *Aspergillus* is determined by immune status of the individual, genetic susceptibility, and quantity and virulence of inhaled *Aspergillus*.
3. Allergic bronchopulmonary aspergillosis (ABPA) occurs in settings of asthma and cystic fibrosis.
4. High index of suspicion with early diagnosis of ABPA is crucial to start aggressive treatment for prevention of irreversible lung damage.
5. Oral prednisolone is the mainstay of treatment for ABPA in asthma and CF with itraconazole being a useful adjuvant therapy.
6. Invasive aspergillus is a notorious disease among immunosuppressed individuals, that needs early diagnosis and treatment.

Chapter 33.5

Cryptococcosis

Ankit Parakh

Cryptococcosis is caused by fungi that belong to the genus *Cryptococcus*. *Cryptococcus* is found in the soil throughout the world, usually in association with large amounts of bird droppings. Cryptococcosis predominantly involves the central nervous system (CNS), lungs, skin, and bones, but other organs can also be affected. Although most cases occur in immunocompromised patients, the systemic disease may occur in seemingly immunocompetent individuals.

ETIOLOGY

Cryptococcus neoformans and *C. gattii* are basidiomycetous, encapsulated yeasts. *C. neoformans* and *C. gattii* can be sub-classified into four serotypes and two species with two varieties. The serotypes are based upon capsular agglutination reactions and are designated A, B, C, or D. Serotype A and D cryptococci were previously classified under the species *neoformans*. However, it has been proposed that the serotype A cryptococci be considered as a separate variety based upon genotypic differences. Serotype A cryptococci are now considered variety *C. grubii*; serotype D are classified under *C. neoformans* and they are divided into four molecular types (VNI, VNII, VNIII, VNIV). Serotypes B and C are now considered separately as *C. gattii*.

PATHOPHYSIOLOGY

Cryptococcal infection is usually acquired by inhalation of the fungal spores, although rarely cutaneous and ocular cryptococcosis has been reported with local inoculation. Infection in the immunocompetent host is usually limited to the lung. Pulmonary infection has a tendency toward spontaneous resolution and is frequently asymptomatic. Silent hematogenous spread to the brain leads to clusters of cryptococci in the perivascular areas of cortical gray matter, in the basal ganglia, and, to a lesser extent, in other areas of the CNS. In chronic cases, a dense basilar arachnoiditis is typical. Lung lesions are characterized by subpleural lesions, which contain yeast forms and have intense granulomatous inflammation.

CLINICAL PRESENTATION

Pulmonary Cryptococcosis

Although the lung is the most common portal of entry for infection, pulmonary cryptococcosis is uncommon in children. One-third of pulmonary infections are asymptomatic. Approximately, half of patients have cough or chest pain, and smaller percentages have sputum production (30%), weight loss (25%), fever (23%), and hemoptysis (20%). In Immunocompromised hosts, the onset may be more severe, and the course more rapid. Radiographic lesions in nonimmunosuppressed hosts include well-defined, noncalcified, single or multiple nodules, mass like infiltrates, hilar lymphadenopathy, pleural effusions, and lung cavitations. In immunosuppressed hosts, radiographic findings include poorly localized bronchopneumonia, lobar consolidations, alveolar and interstitial infiltrates.

Central Nervous System Cryptococcosis

Subacute or chronic meningitis is the most common manifestation of disseminated cryptococcal disease in children.

Meningitis occurs in more than half of cryptococcal infections affecting HIV-infected children. Headache, fever, nausea and vomiting are the usual symptoms. Neck rigidity is seen in 75% of patients who are not immunocompromised and in 33% of patients with HIV. Other, less frequent manifestations include alteration of consciousness, impaired mental function, cranial nerve lesions, visual deficits, papilledema, seizures, diplopia, focal neurologic deficits, photophobia, and abnormal cerebellar signs. The duration of symptoms before a diagnosis is established ranges from less than 1 week to 18 months and tends to be shorter in patients with HIV. The prognosis is better, if the disease is picked up early. Mortality is high up to 15–30%, especially in HIV-positive children. Relapses are described in immunocompromised children although rare with immunocompetent children. Postinfectious sequelae are common and include hydrocephalus, vision loss, cranial nerve deficits and seizures.

Cutaneous Cryptococcosis

Varied manifestations are described including ulcers, nodules, vesicles, abscesses, papules, and purpuric and sinus tracts. Skin lesions usually represent metastases to the skin of a disseminated infection, although local infections have been described. They can be difficult to diagnose clinically given the myriad presentations. Biopsy of the skin lesions with histological examination and culture is required.

DIAGNOSIS

High index of suspicion is required for diagnosis of *Cryptococcus* infections in children. Fever and headache in a child with known HIV or having risk factors for HIV suggest the possibility of *Cryptococcus*, *Toxoplasma* or CNS lymphoma. Evidence of a focal lesion on imaging is unusual in cryptococcal meningitis. In immunocompetent children, the diagnosis is difficult and is usually not considered. Child presenting with chronic meningitis should be evaluated for tubercular (TB) meningitis, *Acanthamoeba* and *Cryptococcus*. Cryptococcal meningitis is an important differential diagnosis in children with TB meningitis who are not responding to first-line anti-TB drugs. Lumbar puncture is the single most important test. Pleocytosis is seen in cerebrospinal fluid (CSF) but rarely exceeding 100 cells/mm³, glucose is reduced to less than 50 mg/dL, and proteins are raised. The findings are less pronounced in children with HIV. The samples should be subjected to direct smears with special stains, Cryptococcal antigen for rapid diagnosis and cultures.

C. neoformans may be shown by direct examination of clinical specimens from CSF, urine, sputum, bronchoalveolar lavage fluid, or aspirates of skin lesions using India ink preparations, Gram staining of smears of cytocentrifugated specimens, or special stains like mucicarmine and Masson-Fontana silver stains, which distinctively show the cell wall and the capsule of the organism.

During cryptococcal meningitis, the India ink CSF preparation reveals the yeast in 80% of cases in HIV-positive children and 50% of uninfected children. For rapid diagnosis of cryptococcal disease, especially meningitis, WHO has recommended the use of cryptococcal antigen tests; either latex agglutination or lateral flow assay should be used. These have a very high sensitivity and specificity. Serum can be tested for the same antigens, if CSF is not available. These are now being considered as point-of-care tests for diagnosis of cryptococcal meningitis. *C. neoformans* can be isolated in most routine mycologic or bacteriologic media, especially chocolate agar, Sabouraud agar and niger seed agar medium. The culture yields the organism in 87–100%.

TREATMENT OF CRYPTOCOCCAL DISEASE (TABLE 1)

The factors that need to be considered in guiding treatment of cryptococcosis are the degree of immunosuppression and extent of infection (pulmonary or extrapulmonary with and without meningitis). Limited data exists from pediatric literature and most of the recommendations are obtained from extrapolation of adult studies.

Treatment of Cryptococcosis in Immunocompetent Hosts

Central Nervous System Disease

For cryptococcal meningitis, a combination of amphotericin B (0.7–1 mg/kg/day), and flucytosine (100 mg/kg/day) is used as induction therapy for 2 weeks, followed by fluconazole (12 mg/kg/day) for 10 weeks. Alternatively, the amphotericin B and flucytosine combination may be continued for 6–10 weeks. The CSF should be examined after the first 2 weeks of therapy, at which time, 75% of patients have sterile CSF. A positive culture at this point is an indication for extending the treatment course beyond the minimum recommendation. Intraventricular and intrathecal amphotericin B may be needed for refractory cases. Lipid formulations of amphotericin B can be used in place of amphotericin B in patients with renal dysfunction, with similar therapeutic efficacy. Regardless of the initial regimen, some experts recommend a subsequent course of fluconazole, 3–6 mg/kg/day for 6–12 months. Treatment outcome is poor, if CNS disease is not recognized and treated early.

Pulmonary Disease

Pulmonary cryptococcal infection may resolve without treatment in immunocompetent hosts. These can be only observed; however, this approach should be considered only when the patient can be followed up closely. Most children however would need treatment given the potential for dissemination, the seriousness of CNS involvement, and the availability of effective and well-tolerated antifungal agents. Performing a lumbar puncture is mandatory in all cases of pulmonary

disease. Immunocompetent patients with asymptomatic and mild-to-moderate disease should be treated with fluconazole, 3–6 mg/kg/day for 3–6 months for asymptomatic disease or 6–12 months for mild-to-moderate disease. Itraconazole is an alternative drug though not preferred. If oral azoles cannot be taken, or progression of the disease occurs, amphotericin B, 0.4–0.7 mg/kg/day, is recommended. Severe pulmonary disease is treated similar to CNS disease.

Treatment of Cryptococcosis in Immunocompromised Hosts with AIDS

Cryptococcal Pneumonia

All HIV-infected patients with pulmonary cryptococcal infection must be treated because they are at high-risk for developing disseminated infection. For children with mild-to-moderate disease, treatment with fluconazole alone is appropriate and should be followed by prophylaxis. For patients with severe pneumonia, amphotericin B should be used until the patient is asymptomatic, at which time, fluconazole can be substituted for maintenance therapy. Patients with cancer and pulmonary cryptococcosis treated with fluconazole monotherapy generally had good outcomes.

Cryptococcal Meningitis

For meningeal cryptococcosis, induction therapy consists of a combination of amphotericin B (0.7–1.0 mg/kg/day) and flucytosine (100 mg/kg/day) for a minimum of 2 weeks. Induction is followed by consolidation treatment with fluconazole (12 mg/kg/daily) for a minimum of 10 weeks, or until CSF cultures are sterile. Because of the relapse rate of 50%, maintenance therapy is important after an acute episode of meningitis in HIV-infected individuals. Fluconazole given daily is the preferred drug for maintenance. Oral itraconazole or amphotericin B given one to three times weekly are alternative maintenance regimens.

Standard management principles of elevated intracranial pressure in children with cryptococcal meningitis include measurement of the CSF pressure and frequent therapeutic lumbar punctures. Neurosurgical procedures like ventricular shunting may be required in severe cases to control cerebral edema or hydrocephalus.

Table 1 Treatment of cryptococcal disease in children

Host	Site of disease	Primary	Secondary
Immunocompetent	Pulmonary or other extrapulmonary	Observation only might be considered Fluconazole, 3–6 mg/kg/day for 3–6 month for asymptomatic disease or 6–12 month for mild-to-moderate disease <i>Alternate:</i> Itraconazole	Amphotericin B, 0.4–0.7 mg/kg/day
	CNS	<i>Induction therapy:</i> Amphotericin B, 0.7–1 mg/kg/day with flucytosine, 100 mg/kg/day for 2 weeks; <i>Maintenance:</i> Fluconazole, 12 mg/kg/day for 10 weeks. <i>Alternate:</i> Amphotericin B and flucytosine combination for 6–10 weeks	Intraventricular and intrathecal amphotericin B may be needed for refractory cases.
Immunocompromised	Pulmonary or other extrapulmonary	All should be treated Fluconazole, 3–6 mg/kg/day for 3–6 m for asymptomatic disease or 6–12 m for mild-to-moderate disease <i>Alternate:</i> Itraconazole <i>Severe cases:</i> Amphotericin B, 0.4–0.7 mg/kg/day Fluconazole prophylaxis	Amphotericin B, 0.4–0.7 mg/kg/day
	CNS	<i>Induction therapy:</i> Amphotericin B, 0.7–1 mg/kg/day with flucytosine, 100 mg/kg/day for 2 weeks; <i>Maintenance:</i> Fluconazole, 12 mg/kg/day for 10 weeks. In case flucytosine is not available, use combination of amphotericin B and fluconazole <i>Alternate:</i> Amphotericin B and flucytosine combination for 6–10 weeks Fluconazole prophylaxis	Intraventricular and intrathecal amphotericin B may be needed for refractory cases.

Immune Reconstitution Inflammatory Syndrome

Immune reconstitution inflammatory syndrome (IRIS) has been described in adult and pediatric patients coinfecting with HIV and *C. neoformans* who are treated with highly active antiretroviral therapy (HAART). Patients with *C. neoformans*-related IRIS present with higher CSF opening pressures, glucose levels, and cell counts. Hence, immediate antiretroviral therapy (ART) initiation is not recommended in HIV-infected children with cryptococcal meningitis due to high risk of IRIS which might be life-threatening. ART initiation should be deferred until there is evidence of a sustained clinical response to antifungal therapy and after 2–4 weeks of induction and consolidation treatment with amphotericin B-containing regimens combined with flucytosine or fluconazole (after 2 weeks with nonmeningeal disease).

In children more than 5 years of age with successfully treated cryptococcal disease (meningeal and nonmeningeal), discontinuation of antifungal treatment maintenance is recommended, if the child had received prophylaxis for 1 year and has CD4 count more than 200 cells/mm³ (two measurements 6 months apart). In HIV-infected children aged between 2 years and 5 years, with successfully treated cryptococcal disease discontinuation of antifungal treatment maintenance is recommended, if the child is stable and adherent to ART and antifungal maintenance treatment for at least 1 year and with a CD4 cell count percentage greater than 25% or absolute count more than 750 cells/mm³ (two measurements 6 months apart). Maintenance treatment with should not be discontinued in children less than 2 years of age.

IN A NUTSHELL

1. Cryptococcosis is a fungal infection which predominantly involves the CNS, lungs, skin, and bones, but other organs can also be affected.
2. It usually affects immunocompromised children but can occur in immunocompetent children.
3. Subacute or chronic meningitis is most common manifestation of disseminated cryptococcal disease in children.
4. Cryptococcal antigen tests on CSF have a high sensitivity and specificity for diagnosis and now considered point-of-care tests.
5. Amphotericin B remains the drug of choice for induction followed by fluconazole for completion of therapy.

Chapter 33.6

Coccidioidomycosis

James Homans, Yee Aye

Coccidioidomycosis is caused by two related fungi, *Coccidioides immitis* and *Coccidioides posadasii*, which have identical manifestations but different geographic distribution. *Coccidioides spp.* (heretofore, *Coccidioides*) are endemic only in the Americas, *C. immitis* in California, Baja California and Arizona, and *C. posadasii* in Arizona, Mexico and parts of Central and South America. Coccidioidomycosis has existed in the Americas since prehistory. It was first described by Posadas in Argentina in 1892 and recognized as a fungus by Ophuls and Moffitt in 1900. *Coccidioides* causes a wide range of disease in humans and domestic and wild mammalian species including dogs, cats, horses, rhinoceri, great cats and dolphins.

ORGANISM

Coccidioides species are found in areas that are hot and dry most of the year with intermittent periods of abundant rainfall. They are dimorphic fungi, assuming two forms depending on their environment (**Fig. 1**). In nature *Coccidioides* exist in saprobic form as soil molds while in animal hosts take a parasitic yeast-like form. The mold produces arthroconidia (arthrospores), hardy spores that break off from the parent mycelium and are transported on air currents. When airborne arthroconidia arrive in the tissue of an animal host, they germinate into spherules filled with endospores. When spherules rupture, endospores disseminate throughout the host, each one capable of producing a new spherule.

EPIDEMIOLOGY

Coccidioidomycosis usually occurs due to inhalation of arthroconidia but can also be inoculated percutaneously. Rarely exposure can occur nosocomially as by exposure to mold on a cast, and accidentally in laboratories. Coccidioidomycosis occasionally occurs outside of endemic areas due to exposure to fomites harboring arthrospores, or in travelers who have recently returned from endemic areas. Incidence and range of infection are increased in periods of increased airborne carriage such as storms and earthquakes, and with increased germination as after heavy rains.

The risk of coccidioidal infection depends on the intensity and duration of exposure. In endemic areas a large proportion of the population has evidence of past infection but only a small proportion has a history of symptomatic disease. Evidence of infection is highest among groups having the highest environmental exposure. However, even a brief exposure, such as car travel through an endemic area, can cause infection. It is thought that inhalation of a single arthrospore can lead to infection.

While risk of infection depends on exposure, the likelihood of developing severe or disseminated infection is affected by genetic predisposition as reflected by ethnic or racial group (Filipinos, African Americans and Hispanics have a markedly higher risk), immune status (deficient cell-mediated immunity leads to a higher risk), and sex (males have a higher risk). Extremes of age, pregnancy, poorly controlled diabetes mellitus, HIV infection, hematologic malignancies and immunosuppressive therapy increase the risk of severe coccidioidomycosis. Past infection usually leads to long-standing protective immunity. Patients with vigorous response to antigen exposure (coccidioidin) by positive skin test are less likely to develop severe disease. Children living

in endemic areas are at risk for infection and have risk factors for severe disease similar to adults. Congenital infection is rare.

PATHOGENESIS

Inhaled arthroconidia penetrate the alveoli and germinate into spherules. Their presence provokes a vigorous and complex immune response. Neutrophil migration and antibody production occur but are ineffective. Cell-mediated immunity, in particular TH1 response, is most important in control of infection. Similar to tuberculosis, there may be extensive extrapulmonary lymphohematogenous dissemination despite initial immunologic control. Tissue inflammation is mainly granulomatous sometimes with caseation.

CLINICAL FEATURES

Most coccidioidal infections are asymptomatic or have mild upper respiratory symptoms, 40% lead to self-limited flulike illness, characterized by cough, fever, malaise, myalgia, pneumonia, and maculopapular rash or erythema nodosum, 5% develop progressive pulmonary disease and 1% extrapulmonary disease.

Pneumonia

Pneumonia is almost always present in primary disease. *Coccidioides* is one of the causes of atypical pneumonia and is frequently misdiagnosed. Disease severity ranges from mild flulike illness to severe pneumonitis with adult respiratory distress syndrome (ARDS). Various infiltrate patterns can be present on chest radiograph including lobar, bronchoalveolar, reticulo-nodular, hilar adenopathy, thin-walled cavities and pleural effusion. A miliary pattern suggests lymphohematogenous seeding. In immunocompetent patients coccidioidal pneumonia frequently resolves without specific treatment. In some cases it may progress slowly to chronic pneumonia with fibrosis.

Extrapulmonary Manifestations

These are usually due to lymphohematogenous dissemination. The most frequently affected sites are skin, soft tissue, abdomen, bones and joints, and meninges. Meningitis and osteoarticular disease (involving tibia, vertebrae, skull, metatarsals and metacarpals) are difficult or impossible to eradicate. Draining fistulas may form. In contrast to pyogenic or tuberculous meningitis, coccidioidal meningitis progresses slowly. Fungemia is associated with high mortality. Reactivation of dormant infection can occur in immunocompromised patients.

APPROACH TO DIAGNOSIS

Clinical suspicion is essential for diagnosis of coccidioidomycosis. Skin testing with coccidioidal antigens is useful as an epidemiologic tool to detect past infection but not as a clinical test for current infection. Serologic testing is the mainstay of diagnosis. The usual test for established disease is *Coccidioides* complement fixation (CF), detecting IgG, which can be obtained on both blood and CSF. Anticoccidioidal IgG is not protective. Higher CF titers (greater than 1:16) suggest disseminated disease and should usually prompt antifungal treatment. Complement fixation titers can also be used to follow disease course. Detection of IgM antibodies is useful in the diagnosis of early disease. Immunodiffusion can also be used to detect either IgG or IgM but is time-consuming. Spherules and rarely mycelia can be detected in clinical specimens using fungal preparations (**Figs 2A to C**). *Coccidioides* grows readily on laboratory media from culture of clinical specimens. Definitive identification is by exoantigens or nucleic acid probes. Isolation of *Coccidioides* from a host with a consistent disease process is diagnostic.

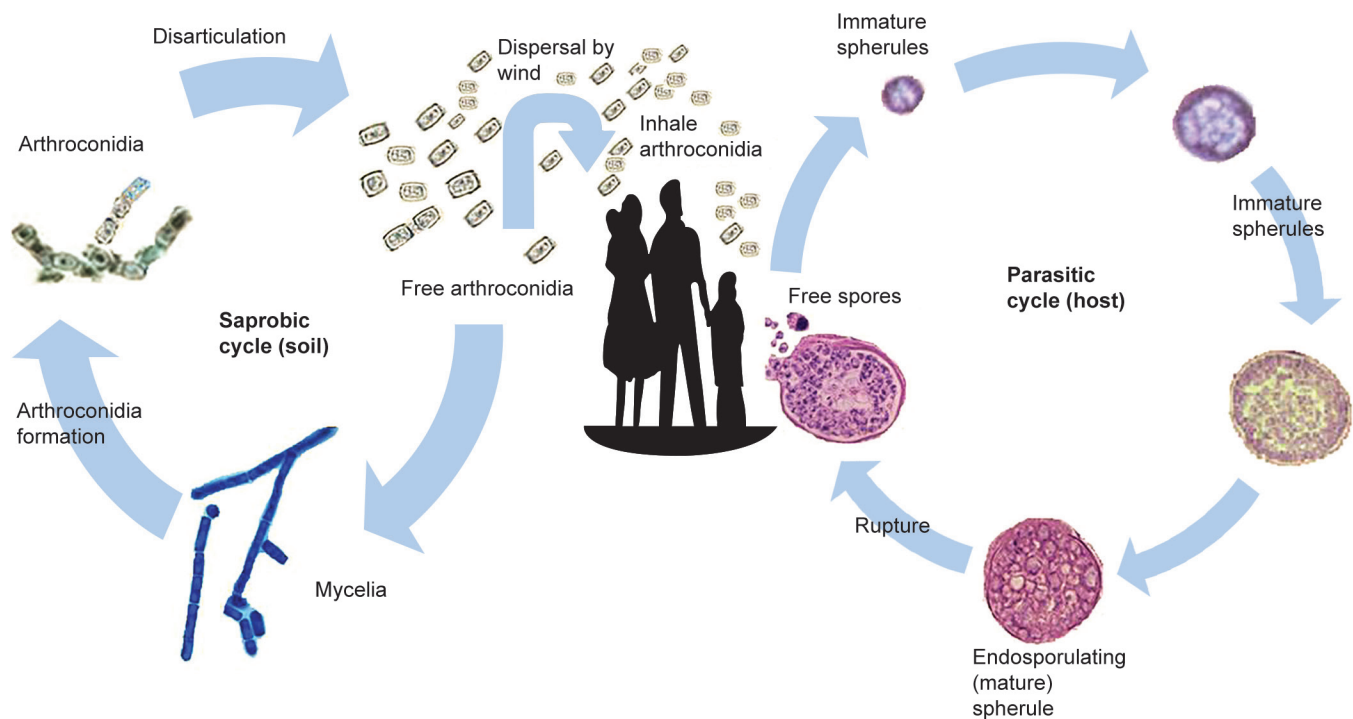

Figure 1 Schema of saprobic and parasitic phases of life cycle of *Coccidioides* spp.

Saprobic cycle: Hair-like mycelia with branching septate hyphae develop into arthroconidia (arthrospores). Arthrospores disarticulate into single arthroconidia (3–5 microns) and remain viable for long periods. In soil arthroconidia grow into mycelia and complete saprobic cycle. Wind and other events lift arthroconidia into the air where they can travel long distances. **Parasitic cycle:** Hosts (human, animals) inhale arthroconidia which change form into thick-walled structures called immature spherules. These mature and fill with endospores. They eventually rupture and release endospores. Each endospore can develop into a spherule completing the parasitic cycle

Figures 2A to C Specimens from a 19-year-old male coccidioidal lymphadenitis and pneumonia from excisional lymph node biopsy. (A) Hematoxylin and eosin stain demonstrating endosporulating *Coccidioides* spherules (1000X magnification); (B) Septate mycelium with arthrospore formation; (C) Culture of *Coccidioides immitis* showing floccose grayish-white colony

Source: Dr Rosemary She

Pneumonia

Chest radiograph can show various patterns, but reticulonodular infiltrates, thin-walled cavities and hilar adenopathy are suggestive (**Figs 3A and B**). Culture of sputum, endotracheal aspirate or bronchoscopy specimen, will frequently grow *Coccidioides*. Serologic testing supports the diagnosis if positive but should not be relied upon for exclusion.

Meningitis

Diagnosis of coccidioidal meningitis relies on clinical suspicion, radiologic studies, and appropriate testing of CSF. Opening pressure

should be performed. Lumbar CSF in coccidioidal meningitis will usually show pleocytosis (50–200/mm³) with lymphocyte predominance, markedly elevated protein and decreased glucose (**Table 1**). Eosinophilia is frequently present. CSF serology is not sensitive enough to exclude disease. Presence of fungal elements, spherules or hyphal elements, on CSF microscopy is suggestive of a high fungal burden. Positive CSF serology (usually CF) or culture for *Coccidioides* is diagnostic. Brain imaging by CT or MRI may range from normal to obstructive hydrocephalus with transependymal edema.

Figures 3A and B A 14-year-old male with coccidioidal pneumonia. (A) Chest radiograph shows bilateral interstitial lung disease and hilar prominence. Right upper lobe opacity may represent atelectasis; (B) Computerized tomography (CT) scan shows ground glass attenuation throughout all lobes of lungs with a central prominence

Table 1 Typical cerebrospinal fluid (CSF) findings in children with meningitis caused by *Coccidioides* and other microorganisms

CSF	Cell count (WBC/mm ³)	Neutrophils	Predominant cell types	Protein (mg/dL)	Glucose (mg/dL)	Stain	Comment
Normal	0–20‡	0–5%	Lymphocytes or monocytes	< 45£	2/3 of serum	No organisms	Several PMNs in a neonatal patient's CSF can be normal
Coccidioidal	< 500	< 10–20%	Lymphocytes, monocytes sometimes eosinophils	> 100–200	< 1/2 of serum	Rarely spherules or hyphal elements	
Fungal	< 500	< 10–20%	Lymphocytes, monocytes	> 100–200	< 1/2 of serum	Rarely hyphal elements	<i>Cryptococcus</i> , histoplasmosis, blastomycosis
Tuberculous	< 500	< 10–20%	Lymphocytes, monocytes	> 200–300	< 1/2 of serum	AFB stain rarely positive	May have mononuclear cells predominance
Viral	100–1,000 (mostly < 500)	20–40%	Lymphocytes	N or < 100	N or < 1/2 of serum	No organisms	PMNs predominate early in course
Bacterial	1,000–5,000 (range < 100 to > 10,000)	> 50–90%	PMNs	> 100–500	< 1/2 of serum	Gram stain sometimes positive	< 500 WBC/mm ³ can be seen in severe or rapid onset pneumococcal meningitis

Abbreviations: CSF, cerebrospinal fluid; WBC, white blood cells; PMNs, polymorphonuclear leukocytes; N, normal

‡ Normal CSF may contain up to 30 leukocytes/mm³ in newborn

£ CSF protein may have up to 150 mg/dL in neonate

Osteomyelitis

Coccidioidal osteomyelitis is suggested by radiologic evidence of bone inflammation or destruction, usually radiolucencies, in a patient with known or suspected coccidioidal infection. Radiological features are shown in **Figures 4A to C**. Confirmation is by demonstration of spherules in biopsy or growth of *Coccidioides* on culture of biopsy material.

MANAGEMENT (TABLE 2)

The first step in the management of primary coccidioidomycosis is deciding whether to treat. Though not proven to be effective in preventing severe disease, treatment of immunocompetent patients with primary coccidioidomycosis should be considered, especially those in high-risk demographic groups. Immunocompromised patients with primary infection should be given a course of antifungal treatment to prevent severe disease.

Figures 4A to C X-rays from 9-year-old boy with multifocal coccidioidal osteomyelitis with fistulous tracts. (A) Expansile lytic lesion in left fourth middle phalanx with cortical destruction and adjacent soft tissue swelling; (B) Lytic lesion in right femoral epiphysis medially with adjacent soft tissue swelling; (C) Lytic lesion in right calcaneus bone at distal heel with adjacent soft tissue swelling

Table 2 Medical and surgical management of coccidioidal disease

Disease process	Medical management	Treatment of fulminant or rapidly progressive infection	Salvage therapy	Surgical management	Estimated duration of therapy
[§] Primary coccidioidomycosis	May not require treatment but consider on case-to-case basis				Observation for 6–12 months
Progressive or complicated pulmonary	Itraconazole Fluconazole	Amphotericin (Ampho) B followed by azole Ampho B + azole	Voriconazole Posaconazole	Ruptured cavity Persistent or enlarging nodules symptomatic cavity, Empyema hydro-pneumothorax	3–6 months Chronic, diffuse cases may treat ≥ 12–24 months
Lymphadenitis	Fluconazole Itraconazole	Ampho B followed by azole	Voriconazole Posaconazole		3–6 months if persists, may treat up to ≥ 12–24 months
Disseminated (non-meningeal)	Fluconazole Itraconazole	Ampho B followed by azole Ampho B + azole	Voriconazole Posaconazole Caspofungin Caspofungin + Fluconazole Caspofungin + Voriconazole		≥ 6 months; For refractory cases ≥ 12–24 months
Skin and soft tissue	Fluconazole Itraconazole	Ampho B followed by azole	Voriconazole Posaconazole		3–12 months
Musculoskeletal	Itraconazole [¶] Fluconazole	Ampho B followed by azole Intra-articular ampho B + azole	Voriconazole Posaconazole	-High CF titer (≥ 1:128) Extensive destructive lesions, large abscesses, progressive tissue destruction, bony sequestrations, vertebral instability, or impingement on critical organs	Range 6–12 to 24 months
Meningitis	Fluconazole Itraconazole	Ampho B + azole Intrathecal ampho B +/- azole	Posaconazole Voriconazole	Obstructive hydrocephalus May require ventriculo-peritoneal shunt	Lifelong with azoles

[§]Healthy patients without evidence of extensive coccidioidal infection or risk factors for more serious infection may not need antifungal therapy. However, it is important that such patients be followed for a year or longer to monitor for the development of complications.

[¶]Osteoarticular infections may respond better to itraconazole treatment than to fluconazole treatment.

Medical Treatment

Treatment of coccidioidomycosis relies on antifungal drugs with appropriate surgical interventions. Amphotericin B, including lipid-based preparations, remains the drug of choice in severe pneumonia or disseminated disease. Fluconazole is an excellent treatment for both systemic and meningeal disease due to excellent anticoccidioidal activity, excellent oral and intravenous bioavailability, excellent meningeal penetration and a favorable toxicity profile. Itraconazole is possibly superior to fluconazole for treatment of nonmeningeal disease. Voriconazole and posaconazole have also been reported effective in refractory cases with fluconazole resistance. Echinocandins have been used in refractory cases.

Surgical Treatment

Surgical intervention is frequently necessary in the management of coccidioidomycosis. The most common interventions include incision and drainage/debridement of abscesses and infected bone and joints. In some cases, reconstructive surgery becomes necessary. CSF diversion by ventriculoperitoneal shunting is frequently necessary in obstructive hydrocephalus.

PROGNOSIS

Most coccidioidomycosis can be managed effectively. Most nonmeningeal disease can be cured with adequate courses of antifungals and judicious surgery to drain abscesses and remove infected tissue. Patients with incurable disease can be maintained on suppressive therapy for many years. Immunocompromised patients may have more severe initial disease, are more difficult to treat and have poorer outcomes.

IN A NUTSHELL

1. Likelihood of coccidioidal infection depends on level and duration of exposure, while likelihood of developing coccidioidal disease depends on patient characteristics including genetic predisposition, age, sex, pregnancy and immune status.
2. Most coccidioidal infections are asymptomatic or minimally symptomatic and resolve without treatment.
3. *Coccidioides* species can cause severe pulmonary and extrapulmonary infections including pneumonia, adult respiratory distress syndrome (ARDS), fungemia, septic shock, meningitis, osteomyelitis and, septic arthritis.
4. Diagnosis of coccidioidal infection entails a high index of suspicion, astute clinical evaluation, appropriate radiologic studies, appropriate laboratory studies such as serologic testing for IgG and IgM of blood or CSF, fungal stain and culture of clinical specimens, in some cases polymerase chain reaction (PCR) or other molecular techniques.
5. Treatment of coccidioidal infection entails antifungal therapy with azole antifungals or amphotericin B preparations, respiratory and hemodynamic support in severe cases, and judicious surgical intervention.

Chapter 33.7

Blastomycosis

G Raghurama Rao

Blastomycosis is a relatively uncommon chronic mycosis caused by inhaling conidia of the dimorphic fungus, *Blastomyces dermatitidis*. All age groups are susceptible to blastomycosis. There are three clinical forms of the disease: pulmonary, disseminated and primary cutaneous blastomycosis.

THE AGENT

Blastomyces dermatitidis exists in nature as a mold. In human and animal tissues it forms large, round budding yeast cells. The natural habitat of *B. dermatitidis* is the soil. Higher soil temperatures and recent rainfall facilitate growth of the fungus. *B. dermatitidis* also occurs in decaying wood and other organic materials including bird guano and animal excreta, forest or sandy soils, water ways, ponds and river banks.

EPIDEMIOLOGY

Blastomycosis is endemic in the South Eastern and South Central United States and Great Lake region. It was originally referred to as North American blastomycosis but the term is misleading as *B. dermatitidis* has a worldwide distribution. Cases of blastomycosis have been documented in at least 15 African countries as well as in Europe, South America, the Middle East, South Asia and India. In India, blastomycosis is a rare disease. The first case of blastomycosis was reported from Uttar Pradesh in 1983. Thereafter, several cases of blastomycosis in humans and animals have been reported mainly from the states of Uttar Pradesh, Delhi, Madhya Pradesh, Tamil Nadu, Karnataka and Andhra Pradesh. There is no well-defined endemic area of blastomycosis in India.

Host factors *Blastomyces dermatitidis* infection was formally thought to be more prominent in men, but women are also equally affected. All age groups are susceptible but majority of the patients are in 20–70 age groups. Children constitute 3–10% of total cases of blastomycosis. Two patients in the perinatal period have been reported. Recently one case of disseminated blastomycosis in a 4-year-old boy and another case of cutaneous blastomycosis in an 8-year-old boy were reported from Andhra Pradesh and Delhi, respectively. In India, these cases are usually mistaken for tuberculosis and under reported. The disease often occurs in individuals with an outdoor occupation such as construction or farming or recreational interest or playing in the dusty atmosphere. In contrast to other fungal infections usually seen in immunocompromised patients, as an opportunistic infections, *B. dermatitidis* is a true pathogen and often affects immunocompetent individuals.

PATHOGENESIS

Inhalation of *B. dermatitidis* spores is the usual mode of infection in humans. Occasional cases have followed traumatic cutaneous inoculation. Other uncommon ways of transmission are transplacental infection of newborn, postmortem transmission at autopsy and venereal transmission. The median incubation period for inhalation (pulmonary) blastomycosis ranges from 30 days to 40 days and for primary cutaneous blastomycosis is 14 days.

Following inhalation, conidia transform into yeasts and induce an inflammatory response with mixed abscess or granuloma in the alveoli. Alveolar macrophages can inhibit the transformation of conidia into yeasts and neutrophils are also active. The process is further influenced by lung surfactant in a complex interplay of

local factors of immunity. T-lymphocytes are the chief mediators of immunity to *B. dermatitidis*. Especially, the Th1 response is primarily responsible for effective immunologic control of infection. The humoral immune system is not significant. Yeasts are relatively resistant to phagocytosis and killing. The BAD-1 (blastomycetes adhesion 1) yeast cell wall protein mediates cellular adhesion and is an indispensable virulence factor and the main target for cellular and humoral immunity. BAD-1 suppresses phagocyte release of TNF- α through transforming growth factor- β -dependent and independent mechanisms. Melanin, another virulence factor, protects the fungus from the leukocyte oxidative burst. Dissemination of the disease to the other organs from the primary pulmonary infection can be through blood stream or lymphatics.

CLINICAL FEATURES

Clinical manifestations range from a transient pulmonary infection to chronic pulmonary infection or to more wide spread disseminated disease. In children, lung involvement is followed by that of skin, bone, subcutaneous masses and central nervous system in descending order of incidence.

Pulmonary Blastomycosis

Infection typically occurs by inhalation. Most infections are asymptomatic and resolve without treatment.

Acute pneumonia About 50% of individuals exposed to *B. dermatitidis* spores develop an acute symptomatic flu-like illness characterized by fever, chills, productive cough, myalgia, arthralgia, pleuritic chest pain and weight loss. The radiological findings are nonspecific and include lobar or segmental consolidation, often in the lower lobes. Most of the patients recover after 2–12 weeks of symptoms. Patients with miliary disease, diffuse pneumonitis, or acute respiratory distress syndrome have a mortality of 50–89%. Others with acute blastomycosis fail to recover and develop a chronic pulmonary infection or disseminated infection.

Chronic pneumonia It is the most frequent presentation, with nodular and lobar infiltrates and the symptoms are similar to those of tuberculosis. Spontaneous resolution is unusual. The radiological findings include consolidation, fibronodular interstitial infiltrate, mass lesions, pleural thickening and pleural effusions. Cavitation is uncommon. In immunocompromised patients blastomycosis may cause severe pulmonary disease with high mortality. Up to 80% of patients with pulmonary blastomycosis manifest with skin lesions.

Cutaneous Blastomycosis

The skin and subcutaneous involvement is the second most common manifestation of blastomycosis and is seen in approximately 60% of patients. Although there are reports of disease due to direct inoculation, skin involvement is usually the result of secondary dissemination following lung infection. The lesions tend to be painless and present either as raised verrucous lesions with irregular border or as ulcers (**Fig. 1**). The former, which are more common, begin as small maculopustular lesions that slowly spread to form large nodular or papulonodular lesions with heaped-up borders. These lesions appear on exposed sites, such as face, neck or extremities and can be mistaken for squamous cell carcinoma or other chronic cutaneous infections like tuberculosis. Besides the skin, ulcerative lesions can appear on the mucosa of the nose, mouth and throat.

Primary cutaneous blastomycosis is very rare. Direct cutaneous inoculation manifests as a chancre at the trauma site, sometimes with associated lymphangitis and lymphadenitis which is typically absent in cases of secondary cutaneous blastomycosis. Local lymph nodes are involved in 65% cases. A mixture of verrucous lesions, ulcers, nodules and papules may be seen in primary cutaneous blastomycosis.

Figure 1 Multiple verrucous plaques of blastomycosis

Others

Osteomyelitis occurs in about 30% of patients with disseminated blastomycosis. The spine, ribs and long bones are the most common sites of infection. Arthritis occurs in up to 10% cases. Meningitis and spinal or brain abscess is rare and seen in 1–5% cases of disseminated blastomycosis. Adrenal glands, thyroid, liver, spleen and gastrointestinal tract are sometimes involved. Choroiditis and endophthalmitis have been reported. Blastomycosis in immunocompromised patients carries a high mortality.

DIFFERENTIAL DIAGNOSIS

Tuberculosis of the lung, skin, bone or genital tract, coccidioidomycosis, histoplasmosis of the lung, bone or meninges and mucocutaneous paracoccidioidomycosis and other infections that can be confused with blastomycosis.

DIAGNOSIS

Microscopic examination is a reliable means to identify characteristic broad-based budding of *B. dermatitidis* in tissue wet mounts of the sputum or exudates following potassium hydroxide (KOH) preparation. Culture on Sabouraud's dextrose agar is the gold standard for isolation and identification of the fungus. The diagnosis can also be made by demonstration of budding yeasts on cytopathology or histology of affected tissue. Skin biopsy specimens from cutaneous blastomycosis show pseudoepitheliomatous hyperplasia with intraepidermal microabscess formation and occasional intraepidermal blastomycetic cells. Poorly defined granuloma with multinucleated giant cells with broad based yeast forms is also seen (**Fig. 2**). Complement fixation, immunodiffusion and enzyme-linked immunosorbent assays have low sensitivity and specificity and are not useful.

TREATMENT

Amphotericin B (0.7–1 mg/kg/day) is the drug of choice for newborns and children with severe blastomycosis. Treatment is continued for 1–2 weeks or until improvement is noted, followed by oral itraconazole 10 mg/kg/day (up to 400 mg/day) as step-down therapy, for a total of 12 months. Children with mild to moderate

Figure 2 Multinucleated giant cells with fungal yeast forms

blastomycosis can be treated with oral itraconazole (10 mg/kg/day to a maximum of 400 mg orally per day) for 6 months.

PROGNOSIS

Excellent clinical response (> 90%, with few relapses) is achieved with itraconazole at 200 mg/day for 6 months in immunocompetent patients. Amphotericin B affords cure rates of 97% in uncomplicated disease.

IN A NUTSHELL

1. Blastomycosis is caused by inhalation of spores of dimorphic fungus, *Blastomyces dermatitidis*.
2. There are 3 clinical forms: pulmonary, disseminated and primary cutaneous.
3. The most common organs involved are the lungs, skin, bone and CNS, in that order.
4. Diagnosis is by demonstration of fungus in the tissue, sputum and exudates by potassium hydroxide (KOH) mounts and culture.
5. Amphotericin B is the drug of choice in severe cases and oral itraconazole for mild cases.

Chapter 33.8

Histoplasmosis

S Nivedhana, S Balasubramanian

Histoplasmosis is a systemic granulomatous disease caused by dimorphic fungus *Histoplasma capsulatum*. It is an endemic mycosis and is the most common pulmonary and systemic mycosis throughout the world. The first case was described by Samuel Taylor Darling in 1905, in whose honor it was designated as *Darling's disease*. He named it after observing the intracellular yeasts within the macrophages (histiocytes) which resembled *Plasmodium* and appeared to have a capsule.

EPIDEMIOLOGY

The disease is prevalent worldwide in areas of temperate climate and is endemic in USA, Latin America and Africa. In India majority of cases are reported from eastern and northeastern parts along the gangetic plains. Two distinct varieties of *H. capsulatum* are pathogenic to humans:

1. *H. capsulatum* var. *capsulatum*—distributed worldwide causing classical or small form histoplasmosis
2. *H. capsulatum* var. *duboisii*—restricted to sub-Saharan Africa causing African or large-form histoplasmosis.

The infection is common in rural areas amongst adult men but in children there is no such sex predilection. The soil with high nitrogen content related to droppings of chicken, bats and high humidity acts as the reservoir and the source of infection. The fungi exist in the soil in mold or filamentous form. Man to man transmission is rare. In India the condition might be under diagnosed due to lack of awareness or misdiagnosed as tuberculosis.

PATHOGENESIS

The fungi are inhaled as conidia from the soil and become unicellular yeasts in alveolar macrophages. The yeasts evade the host immune response by attaching to integrin cell surface receptors, enter the neutrophils and macrophages and after altering the intracellular environment, replicate inside them. Successful clearance of infection depends on intact cell-mediated immunity (CMI) and cytokines (TNF- α , IFN- γ , IL-1, IL-4 and IL-12).

If the disease establishes there is extensive granulomatous inflammation with formation of caseating and noncaseating granulomas. Individuals with primary or acquired cellular immunodeficiencies and infants are at higher risk of dissemination to all phagocytic cells of reticuloendothelial system including liver, spleen, bone marrow and lymph nodes. There is frequent bilateral adrenal enlargement. Histopathology of CNS lesions includes granulomatous basilar meningitis and vasculitis.

CLINICAL FEATURES

The infection is asymptomatic in majority of immunocompetent individuals. This is common in endemic areas and is indicated by positive histoplasmin skin test without any focus of infection. Classification of symptomatic infection is based on duration of infection and site of involvement as follows.

Acute Pulmonary Histoplasmosis

Among symptomatic cases, most infections are mild, self-limited with an influenza like illness which resolves in 3–5 days. After exposure to large inocula the symptoms include fever, chills, myalgia, and persistent cough for 2 weeks. If it lasts longer there is weight loss, fatigue and recurrent nonpleuritic chest pain. There might be dyspnea

in diffuse pneumonitis. Complications include mediastinal adenitis, mediastinal granuloma, obstruction of mediastinal structures by enlarged lymph nodes, pericarditis, and mediastinal fibrosis. At later stages, these may be accompanied by acute migratory polyarthritides, erythema multiforme or erythema nodosum.

Chronic or Cavitory Pulmonary Histoplasmosis

This presentation is rare in children. There is formation of apical or subapical cavities with hemoptysis. There may be formation of pulmonary histoplasmoses—granulomas encased in dense fibrous tissue with concentric layers of collagen tissue and subsequent calcification. These enlarge to a size of 3–4 cm over several years and can radiologically mimic pulmonary neoplasms. If left untreated the disease is fatal.

Primary Cutaneous and Mucocutaneous Histoplasmosis

Petechiae or ecchymotic purpura are seen over skin of the abdomen or thorax. In Indians, localized oral cavity ulcers (Fig. 1) are more frequent than pulmonary lesions and skin lesions are found only in few.

Progressive Disseminated Histoplasmosis

This complication occurs in immunodeficient patients and especially in children under 2 years of age. Transplacental infection has also been documented in infants born to women with progressive disseminated histoplasmosis (PDH) complicating AIDS. PDH may either result from exogenous exposure (most common) or reactivation of quiescent endogenous infection. PDH in adults can be classified as acute, subacute or chronic but in children it is always acute, progressive and life-threatening infection. The histoplasmin skin test is negative in children who develop PDH subsequently.

Progressive Disseminated Histoplasmosis of Infancy

The presenting symptoms are fever, cough, oropharyngeal ulcers, tachypnea, lymphadenopathy, hemorrhagic skin lesions, and gastrointestinal bleeding. Hepatosplenomegaly is always present. The lymph nodes, bone marrow, adrenals, and gastrointestinal tract are commonly involved. There is pancytopenia, and disseminated intravascular coagulation owing to extensive involvement of reticuloendothelial cells simulating lymphoreticular malignancy. With appropriate antifungal therapy, survival is excellent.

Figure 1 Oral ulcers in histoplasmosis

Reproduced with permission from Chande C, Menon S, Gohil A, et al. Cutaneous histoplasmosis in AIDS. Indian J Med Microbiol. 2010;28:404-6.

Progressive Disseminated Histoplasmosis in Immunocompromised Hosts

This presentation is seen in patients with immunodeficiency disorders, organ transplantation, chronic renal failure and those on immunosuppressive therapy for hematologic malignancies. In children on chemotherapy PDH occurs as remission or relapse. They present with persistent fever and tachypnea. Chest X-rays show diffuse interstitial infiltrates and there is progressive hypoxemia. But the same clinical picture can also be caused by *Pneumocystis*, cytomegalovirus (CMV) and other opportunistic viral and fungal infections. In the GI tract distal ileum is commonly involved, followed by colon and stomach. These patients usually present with bloody diarrhea, gastrointestinal bleeding and perforation. Meningitis occurs in majority of infants with PDH. In adults, CNS infections manifest as cerebral abscess or chronic meningitis.

Diagnosis is established by *Histoplasma* antigen assay of urine. In cases where the assay is negative, lung biopsy is useful which is also most sensitive and specific. Bronchoalveolar lavage (BAL) fluid examination is useful in adults but not in children.

Progressive Disseminated Histoplasmosis in HIV Patients

Histoplasmosis is an AIDS defining illness and patients with CD4 counts less than 150/ μ L are at increased risk. Prior to the development of highly active antiretroviral therapy (HAART), disseminated disease was present in most of AIDS patients. Gastrointestinal and CNS infection is common in adults. There are only few reports of histoplasmosis in HIV infected children. In AIDS patients with histoplasmosis receiving HAART an immune reconstitution inflammatory syndrome (IRIS) has been described.

Other Infections

CNS symptoms occur in few adults with PDH and include meningitis, encephalitis, cranial nerve palsies and stroke. They are unusual in immunocompetent children. Disseminated meningitis is reported in children with PDH of infancy. *Presumed ocular histoplasmosis syndrome* is a late sequelae of subclinical infection. It is characterized by choroidal scars in macula (histo spots), peripapillary atrophy, and choroidal neovascularization which can lead to loss of central vision. This is rare in children. *African histoplasmosis* has higher tendency to involve bones (skull, ribs) with osteolytic lesions, followed by skin (cutaneous ulcers, papules and nodules) and subcutaneous granulomata and abscess with discharging sinuses. There is lesser frequency of lung or internal organ involvement.

DIFFERENTIAL DIAGNOSIS

Clinical features closely mimic that of tuberculosis. However, radiologically calcification is more common in histoplasmosis than TB. Intracellular yeasts of *Histoplasma* can be confused with *Leishmania donovani* (differentiated by the presence of kinetoplast) and *Toxoplasma gondii* (differentiated by the presence of tachyzoites of *T. gondii*, which are not stained with fungal stains). In tissue sections of AIDS patients *Penicillium marneffei* resembles *Histoplasma* but is differentiated by the presence of transverse dividing fission cells in the former.

DIAGNOSIS

Imaging

The chest radiographs in adults shows small, nodular lesions with enlarged hilar nodes and pulmonary infiltrates. Calcification is seen in later stages. CT scan is more sensitive and clearly delineates parenchymal lesions. Abdominal ultrasound or CT shows bilateral adrenal enlargement in adults. Generally in children, radiographic

findings are not pathognomonic. In radiographs of children with PDH with immunosuppression, diffuse interstitial infiltrates are commonly seen that worsen rapidly with progressive hypoxemia.

Microscopy and Culture

The specimens helpful are sputum, bone marrow, CSF, body fluids, lymph node aspirate/biopsy and blood smears. KOH mount can miss out on tiny yeast cells. With Giemsa staining, the fungus appears as tiny, oval yeasts (2–4 μ) within macrophages and neutrophils. The GMS (Gomori methenamine silver) stain is particularly sensitive as calcification artifacts are dissolved during staining. *Histoplasma* can be cultured onto Sabouraud dextrose agar. Most isolates grow in 3–4 weeks. At 25°C the mycelium grows as fluffy, aerial mycelium that is white or buff brown. On lactophenol cotton blue (LPCB) mount, septate hyphae with small, elliptical microconidia (2–4 μ) are seen laterally attached to the hyphae. Prominent thick walled, tuberculate macroconidia (8–16 μ) are seen from short conidiophore (**Fig. 2**). The sensitivity of culture varies from 40% in acute to 85% in disseminated histoplasmosis. Lysis-centrifugation system is used for recovery of *Histoplasma* from blood and the resulting concentrate is inoculated onto Sabouraud dextrose agar, which shortens the time for growth from 16 days to 9 days.

Antibody Detection

Serological tests become positive usually after 4 weeks of exposure. The antigens used are derived from merthiolated suspensions of whole yeast cells (Y) in saline and mycelial form (M) culture filtrate (H-histoplasmin).

Complement fixation (CF) test Single titer of 1:32 or higher or fourfold increase between acute and convalescent sera is suggestive of recent infection. The CF-Y phase is more sensitive than CF-M phase in recent infection. CF-M phase is more sensitive and specific for diagnosis of isolated meningitis in histoplasmosis.

Micro-immunodiffusion (ID) Detects precipitins against M and H glycoprotein antigens. More specific than CF. Not approved for use in cerebrospinal fluid (CSF) samples. The H band is seen infrequently and it suggests active infection. It is seen less consistently in children. The M band is present in both active and chronic histoplasmosis.

Figure 2 *Histoplasma capsulatum* lactophenol cotton blue (LPCB) mount: Showing tuberculate macroconidia. Reproduced with permission from Baradkar VP, et al. A rare case of *Histoplasma fungemia* in an AIDS patient. Indian J Med Microbiol. 2011;29: 188-91.

Antigen Detection

These are rapid, accurate and noninvasive method for diagnosis of histoplasmosis from serum, urine, CSF and BAL fluid samples. The sensitivity varies from 75% to 81% in acute pulmonary histoplasmosis to 92% in PDH. Extremely useful in immunocompromised patients in whom serological tests are often negative. Utilizes quantitative, third generation enzyme-linked immunosorbent assay (ELISA). Levels should be measured before the start of therapy, at 3–4 months interval during therapy and at the end of therapy. Antigen levels in serum and urine reduce with treatment and become absent after adequate treatment. In cases of relapse, monitoring antigen levels for 1 year is necessary.

Cross reactions may be seen with paracoccidioidomycosis, blastomycosis, penicilliosis marneffeii and African histoplasmosis. False-positive results occur with body fluids containing high protein (pleural, pericardial, peritoneal); therefore these fluids and tissue filtrates are unsuitable for antigen testing.

Histoplasmin Skin Testing

This has been used in the past and is not useful in endemic areas and in patients with disseminated disease. After intradermal injection of histoplasmin antigen (0.1 mL) prepared from mycelial phase, an induration of 5 mm that develops after 48 hour is considered positive. The reactivity develops 2–4 weeks after primary infection and indicates adequate cellular immunity.

Molecular Methods

Specific oligonucleotide probes (Gen-Probe) have been developed for use in clinical specimens. PCR used in clinical samples has 0–22% sensitivity and 80–100% specificity.

TREATMENT

Amphotericin B and itraconazole are the drugs of choice. Treatment plans are detailed in **Table 1**.

Table 1 Treatment of histoplasmosis

Manifestation	Treatment
Acute pulmonary histoplasmosis (Severe illness)	Amphotericin B for 2 weeks, followed by itraconazole for 12 weeks
Disseminated histoplasmosis	Amphotericin B for 2 weeks, followed by itraconazole for 6 months
Isolated meningitis	Amphotericin B for 3 months, followed by itraconazole for 12 months
Rheumatological complications and pericarditis	Nonsteroidal anti-inflammatory drugs (NSAIDs) for 2–12 weeks

Dosage: Amphotericin B—1 mg/kg daily; Itraconazole—5–10 mg/kg in two divided doses.

PROGNOSIS

Histoplasmosis is self-limited in majority of the healthy individuals. In extremes of age and immunocompromised people serious illness occurs. The cure rate is high for children who receive appropriate therapy for serious acute illness. Data to predict the occurrence of long-term complications is currently unavailable.

PREVENTION

Individuals with impaired CMI who reside in or travel to endemic areas must be educated about activities that may result in inhalation of aerosolized spores. If unavoidable, use of NIOSH (National Institute for Occupational Safety and Health) certified mask is recommended. When potentially contaminated sites are being manipulated, the aerosol formation may be reduced by prior dampening of the areas with water. Prophylactic itraconazole may be given to HIV infected persons with exposure to bird droppings.

IN A NUTSHELL

1. Histoplasmosis is an under-recognized entity in India.
2. Histoplasmosis is an AIDS defining condition.
3. Histoplasmosis manifestations are seen primarily in immunocompromised children only.
4. Histoplasmosis should be considered in the differential diagnosis of prolonged fever, oral ulcers and adrenal enlargement.
5. Histoplasmosis should be considered as differential diagnosis in TB patients with granulomatous disease who do not respond to antituberculous treatment (ATT).
6. Antifungal therapy leads to excellent outcome in most patients.

Chapter 33.9

Pneumocystis Jirovecii (previously classified as *P. Carinii*)

Ira Shah, Khushnuma Mullanfiroze

Pneumocystis jirovecii (*P. carinii*) is a ubiquitous parasite and opportunistic resident of the human bronchoalveolar lumen and a variety of other mammalian species. It has some common features of protozoa, but molecular studies have shown greater genetic homology to fungi. *Pneumocystis* organisms are host specific, with those infecting humans designated *P. jirovecii*. This microorganism replicates under immunosuppressive conditions, ultimately resulting in interstitial pneumonia called *Pneumocystis* pneumonia (PCP), which is generally lethal if left untreated. The infection remains localized to the lungs.

Information on prevalence of *Pneumocystis* pneumonia (PCP) in immunocompromised children with pneumonia in Southeast Asia is limited. Most children are believed to have been exposed to the organism by age 3 or 4 years and its occurrence is worldwide.

PATHOPHYSIOLOGY

The 5–7 mm cyst contains up to eight pleomorphic intracystic bodies (sporozoites). Once excysted, sporozoites become trophic forms (trophozoites). Once inhaled, all these forms reside in the alveoli of the lung. The trophic form of *Pneumocystis* organisms attach to the alveoli. Multiple host immune factors, importantly, CD4+ T-cells and macrophages, hinder uncontrolled replication of *Pneumocystis* organisms and subsequent development of illness, in immunocompetent hosts. Therefore in immunocompromised hosts, when activated alveolar macrophages and CD4+ T-cells are unable to eradicate *Pneumocystis* organisms, pneumonia and other manifestations of the disease ensue. Lung injury is directly related to the *P. jirovecii*-specific inflammatory response rather than to the organism burden per se. Thus, there seems to be a role of steroids to control the inflammation and hypoxia in these patients.

Children with primary immune deficiencies, e.g., hypogammaglobulinemia, severe combined immunodeficiency (SCID); HIV infection with low CD4+ T levels; malignancies and those on immunosuppressive therapy are at increased risk of acquiring PCP.

CLINICAL FEATURES

Pneumocystis pneumonia presents with nonspecific respiratory symptoms, including tachypnea and cough. Two somewhat different clinical patterns have been observed.

The endemic infantile form of PCP, originally described in outbreaks in European nursing homes for infants, is an interstitial plasma cell pneumonitis. A bronchiolitis-like illness can occur, with prominent tachypnea and dyspnea in the absence of fever. Intercostal retractions are marked, and as the course progresses, flaring of the nasal alae and cyanosis can be observed, and crackles are heard bilaterally. There may be nonspecific symptoms like anorexia, diarrhea, vomiting and listlessness. The untreated course is prolonged over many days to a few weeks, and at least half of these patients die.

Pneumocystis pneumonia in older children and adults begins abruptly with fever, tachypnea, and cough. Intercostal retractions and flaring of the nasal alae may occur, but breath sounds are normal and rales are not heard. The untreated course is progressive, and all untreated patients die within a month. An occasional older child may have complains of substernal pain.

Pneumocystis pneumonia needs to be differentiated from acute respiratory distress syndrome, cytomegalovirus pneumonitis, lymphocytic interstitial pneumonia (LIP), mycoplasma infections, legionellosis, tuberculosis, and *Mycobacterium avium* complex (MAC) infection.

APPROACH TO DIAGNOSIS

Since initial symptoms are nonspecific, always keep a high index of suspicion in those at risk. Suspect PCP in a clinical setting of immunosuppression (primary or secondary) with signs of respiratory distress and hypoxemia. Chest X-ray shows bilateral diffuse reticulogranular infiltrates (**Fig. 1**). *Pneumocystis* is identified either by staining methods which include Grocott-Gomori silver stain, toluidine blue, polychrome stains, fluorescein-labeled monoclonal antibody stains on specimens such as bronchoalveolar lavage (BAL), tracheal aspirate, transbronchial lung biopsy, bronchial brushings, percutaneous transthoracic needle aspiration or open lung biopsy. PCR analysis of the specimen offers a rapid diagnostic method but is not yet standardized for clinical use. Though hypertonic saline-induced sputum samples may be used, absence of organism in induced sputum samples cannot exclude the infection. Open lung biopsy though most reliable is unacceptable clinically and BAL is the most practical method for acquiring the respiratory sample. Endotracheal tube aspirates for those on mechanical ventilation may also be used for diagnosis.

Some studies have stated the role of estimating serum lactate dehydrogenase (LDH) levels in diagnosis and monitoring treatment of patients with PCP pneumonia. Patients with PCP and an initial markedly elevated serum LDH level or a rising serum LDH level despite PCP treatment have a worse prognosis and decreased survival rate, in some studies.

P. jirovecii persists in the lungs for many days after the onset of specific therapy. Under certain circumstances, such as children with terminal stages of untreatable cancer and patients with uncontrollable bleeding disorders, where diagnostic procedure may not be possible, therapy can be initiated immediately and the procedure performed later.

Severity of PCP grading is based on severity of hypoxia, classified using alveolar-arterial (A-a) gradient as follows: < 35 mm Hg—mild; 35–45 mm Hg—moderate; > 45 mm Hg—severe. Severe disease is also indicated by a room air partial pressure of oxygen PaO₂ lower than 70 mm Hg.

Figure 1 Chest X-ray showing *Pneumocystis* pneumonia (PCP) with basal and perihilar haziness

MANAGEMENT

Supportive Care

As dictated by the clinical condition, supportive care must aim to achieve adequate oxygenation and hydration. 5–10% of AIDS patients might require mechanical ventilation whereas 50–60% of patients without AIDS require ventilation.

Specific Therapy

While officially classified as a fungal pneumonia, PCP does not respond to antifungal treatment, though some reports state successful use of echinocandins recently. Currently, antibiotics are recommended for treatment of mild, moderate and severe PCP. Intravenous or oral trimethoprim-sulfamethoxazole [(TMP-SMX) 15–20 mg/kg/day of TMP and 75–100 mg/kg/day of SMX in four divided doses] has been shown to be as effective as intravenous pentamidine and more effective than other alternative treatment regimens. The parenteral route may be considered in those with serious illness or in those with gastrointestinal side effects. Duration of treatment is 3 weeks for HIV infected children and 2 weeks for other patients. Adverse effects of TMP-SMX are erythema multiforme, Stevens-Johnson syndrome (SJS), bone marrow suppression, hepatitis, and interstitial nephritis. For mild rash, TMP/SMX can be temporarily discontinued and restarted when rash resolves. If SJS occurs, therapy should be discontinued and not restarted.

In cases of nonresponse to TMP-SMX within 5–7 days or non-tolerance, IV pentamidine is used. If intravenous access is not available, the drug can be given by deep intramuscular injection, but serious reactions at the injection site, such as soft tissue necrosis and abscess, are common. Other adverse reactions occur in up to 70% of cases and include renal and hepatic dysfunction, thrombocytopenia, anemia, hypotension, abnormally high or low blood glucose concentrations, and rash. Other alternative drugs include atovaquone, trimetrexate glucuronate or combinations of trimethoprim plus dapsone or clindamycin plus primaquine, pyrimethamine-sulfadoxine and aerosolized pentamidine (**Table 1**).

Corticosteroids

Corticosteroids are used as adjunctive initial therapy in patients with a PaO_2 less than 70 mm Hg or an A-a gradient of 35 mm Hg and greater. Methylprednisolone, 2 mg/kg/day, has been used

in children. The dose should be tapered and the corticosteroid discontinued in the recovery stage of pneumonia. The effect of corticosteroid in this setting is probably modulation of the inflammatory response.

PREVENTION

Patients at risk of PCP must receive chemoprophylaxis. In patients with HIV, PCP prophylaxis is recommended in following situations:

- All HIV exposed infants from 4 weeks of age (infants born to HIV infected mothers) till proven to be HIV negative
- All HIV infected asymptomatic infants till 1 year of age
- All symptomatic HIV infected children (WHO stage 2 and above)
- After initial treatment for PCP
- All HIV infected children with CD4 less than 200 cells/cumm in children above 5 years of age and less than 25% in children below 5 years of age irrespective of symptoms.

How Long to give Prophylaxis?

- In HIV exposed infants till proved to be HIV negative
- In patients on ART, if there is evidence of rise in CD4 count of more than 200 cells/cumm in children above 5 years of age and more than 25% in children below 5 years of age on occasions (at least 3 months apart), consider stopping the prophylaxis
- All HIV infected children who do not receive ART and are symptomatic—prophylaxis should be continued indefinitely.

Due to ease of administration, relative lack of toxicity and established role against PCP, TMP-SMX (5 mg/kg TMP and 25 mg/kg SMX PO once or in two divided doses given for consecutive days a week or on alternate days) is the most commonly used drug for primary and secondary prophylaxis in immunocompromised children. For those intolerant to TMP-SMX, aerosolized pentamidine, atovaquone or dapsone may be used. Dapsone orally at a dose of 2 mg/kg/day or 4 mg/kg once weekly can be used. Dapsone is effective in the prevention of PCP, but adverse reactions similar to those caused by sulfonamides can occur. The total dose should not exceed 100 mg/day or 200 mg per dose weekly.

Table 1 Treatment of *Pneumocystis pneumonia* (PCP)

Drugs	Dosing	Remarks
TMP/SMX	15–20 mg/kg of TMP IV/PO in four divided doses for 21 days	Drug of choice. Shift to oral administration as soon as clinical improvement occurs
Primaquine/clindamycin	Primaquine base 0.3 mg/kg OD PO (max 30 mg/day) + Clindamycin 10 mg/kg IV or PO every 6 hour (max: 600 mg IV, 300–450 mg PO) for 21 days	Alternative therapy. Data in children not available
Dapsone/trimethoprim	Dapsone—2 mg/kg/day OD PO + Trimethoprim 15 mg/kg/day in 3 divided doses PO for 21 days	Limited data in children. Alternative therapy
Steroids	Prednisolone Day 1–5—2 mg/kg/day PO BD Day 6–10—1 mg/kg/day PO Day 11–12—0.5 mg/kg/day PO OR IV/IM Dexamethasone 0.3–0.5 mg/kg 6 hourly for 5 days	Indications: $\text{PaO}_2 < 70$ mm of Hg at room air

PROGNOSIS

Without treatment, PCP is universally fatal, within 3–4 weeks of onset. The mortality depends more on the inflammatory response rather than the organism burden. Patients requiring mechanical ventilation have a higher mortality rate. Patients remain at risk for *P. jirovecii* pneumonia as long as the immunosuppression persists and hence continuous prophylaxis is warranted in most patients.

IN A NUTSHELL

1. Suspect *Pneumocystis* pneumonia (PCP) in any immuno-compromised child with fever, cough and tachypnea.
2. Steroids may be required in patients with PCP and hypoxia.
3. Treatment should be initiated even if definite diagnosis cannot be established due to delay in tests.
4. Patients at risk of PCP must receive chemoprophylaxis.

Chapter 34.1 Epidemiology, Classification, and Approach to Diagnosis of Rickettsial Infections

Narendra Rathi

Rickettsial diseases are unique among all infectious diseases in being one of the most difficult to diagnose and at the same time one of the most easy to treat infections. Difficulty in diagnosis is the result of low index of suspicion, nonspecific signs and symptoms, and absence of widely available sensitive and specific diagnostic tests while ease of treatment is due to rapid defervescence seen with the most inexpensive antibiotics, early in the course of disease. They have been one of the great scourges of mankind, occurring in devastating epidemics during times of war and famine. These infections in the past have taken more lives than all the wars combined together. Rickettsial diseases are some of the most important re-emerging infections of the present times.

EPIDEMIOLOGY

These infections are prevalent throughout the world. Due to low index of suspicion, unavailability of proper diagnostic tests and poor reporting system, reported numbers are always an underestimate in India. Rickettsial disease in India has been documented from Delhi, Jammu and Kashmir, Himachal Pradesh, Uttaranchal, Rajasthan, Assam, West Bengal, Maharashtra, Kerala, Puducherry, Karnataka and Tamil Nadu.

The family rickettsiaceae comprise a group of microorganisms which occupy a place between bacteria and viruses. Rickettsiae are small, nonflagellate, gram-negative pleomorphic coccobacilli and

obligate intracellular parasites. They are transmitted by arthropod vectors, such as lice, fleas, ticks and mites, in which they are found in the alimentary canal. Rickettsia infects vascular endothelium and reticuloendothelial cells. They need tissue cultures and laboratory animals for their isolation as their growth does not occur on cell free media being obligate intracellular pathogens. Transmission to humans occurs by infected arthropod vector or by exposure to infected animal reservoir host. Poorly maintained kitchen garden and long grass, pets infected with vectors, animal sheds in vicinity of houses are important factors for transmission.

PATHOGENESIS

Vasculitis is the basic pathogenetic mechanism and explains clinical features like skin rash, microvascular leakage, edema, tissue hypoperfusion and end-organ ischemic injury. Formation of thrombi can lead to tissue infarction and hemorrhagic necrosis. Inflammation and vascular leakage leads to interstitial pneumonitis, noncardiogenic pulmonary edema, cerebral edema and meningoencephalitis. Infection of endothelial cells also induce procoagulant activity that promote coagulation factor consumption, platelet adhesion and leukocyte emigration and may result in clinical syndrome similar to disseminated intravascular coagulation.

CLASSIFICATION

Family rickettsiaceae comprises three genera namely *Rickettsia*, *Orientia* and *Ehrlichia*. Former members of this family, *Coxiella burnetii* which causes Q fever and *Rochalimaea quintana* causing trench fever have been excluded because the former is not primarily arthropod-borne and the latter not an obligate intracellular parasite. Various members of *Rickettsia* can be grouped into four biogroups based on the lipopolysaccharide group antigen (Table 1).

Table 1 Classification of rickettsial disease

Biogroup	Disease	Vector	Host	Organism
Spotted fever	Rocky mountain spotted fever (RMSF)	Tick	Dogs, rodents	<i>Rickettsia rickettsii</i>
	Rickettsialpox	Mite	Mice	<i>Rickettsia akari</i>
	Indian tick typhus/Boutonneuse fever/Mediterranean spotted fever (MSF)	Tick	Dogs, rodents	<i>Rickettsia conorii</i>
Typhus	Epidemic louse borne typhus	Louse	Human	<i>Rickettsia prowazekii</i>
	Brill-Zinsser disease (recrudescent typhus)	Louse	Human	<i>Rickettsia prowazekii</i>
	Endemic/Murine flea borne typhus	Flea	Rats	<i>Rickettsia typhi</i>
Scrub typhus	Scrub typhus	Chigger	Rodents	<i>Orientia tsutsugamushi</i>
Miscellaneous	Ehrlichiosis and Anaplasmosis	Tick	Deer, dogs, rodents	<i>Ehrlichia</i> , <i>Anaplasma</i>
	TIBOLA (tick borne lymphadenopathy)	Tick	Wild boar	<i>Rickettsia slovaca</i>
	DEBONEL	Tick	Wild boar	<i>Rickettsia slovaca</i>

Abbreviation: DEBONEL, dermacentor borne necrosis-eschar-lymphadenopathy.

INDIAN SCENARIO

In India, the most common Rickettsial infections are Indian tick typhus and scrub typhus. There are some differences in epidemiological aspects among these biogroups. Arthropods maintain the infection naturally by either transovarial transmission (passage of the organism from infected arthropods to their progeny seen in spotted fever group and scrub typhus) wherein arthropods act as vector as well as reservoir; or without transovarial transmission seen in typhus fever group, wherein arthropods act only as vector. Vector to human transmission occurs as vector defecates while feeding (flea feeding reflex) so that feces contaminate pruritic bite wounds (seen with typhus fever group) or primarily by bite, where regurgitation of infected saliva occurs during feeding (seen with spotted fever group and scrub typhus).

DIAGNOSIS

Rickettsial disease should be kept in mind in all cases of fever with rash, fever without focus, pyrexia of unknown origin, fever with edema, dengue-like illness, meningoencephalitis/aseptic meningitis, and infective vasculitis. An algorithm for diagnosis of rickettsial diseases is given in **Figure 1**. Rathi et al. have suggested Rathi, Goodman, Aghai scoring system to diagnose spotted fever rickettsioses using clinical, laboratory and epidemiological features (**Table 2**). This scoring system with a cutoff score 14 (total score 35) has been reported to have high sensitivity (96.1%) and specificity (98.8%), similar to the detection of specific IgM antibody by ELISA (*Indian Pediatrics*, 2011).

IN A NUTSHELL

1. Rickettsial infections are an important zoonoses emerging and re-emerging with high morbidity and mortality if not recognized and treated promptly.
2. High index of suspicion is needed to diagnose rickettsial diseases in nonspecific febrile illnesses on the basis of clinical, laboratory and epidemiological clues.
3. Vasculitis with capillary leak is the basic pathophysiology, and hence these infections present as dengue-like diseases (e.g., dengue fever, leptospirosis, septicemia, etc.).
4. Fever, rash, edema, eschar, hepatosplenomegaly are usual clinical features; and meningoencephalitis, adult respiratory distress syndrome and disseminated intravascular coagulation are the usual complications.
5. Possibility of vector exposure, compatible laboratory features and ruling out differential diagnosis are key elements for diagnosis. In such cases, empirical treatment with doxycycline leading to rapid defervescence in 48 hours clinches the diagnosis.
6. RGA scoring system has been suggested as an important clinical tool for diagnosis of spotted fever group of rickettsiosis.
7. Serological tests like Weil–Felix, ELISA and IFA are useful only after 5–7 days of illness.

Chapter 34.2

Spotted Fevers

Atul A Kulkarni

Spotted fevers are caused by *Rickettsia* spp. in the spotted fever group (SFG), and these are recognized for more than a century. In most of these diseases, clinical signs are similar. However, the clinical signs are mild and self-limiting in some patients while in some others, these can be severe and life-threatening. For many years, it was believed that spotted fevers were caused by a handful number of organisms including *R. rickettsii* (Rocky Mountain spotted fever) in the Americas, *R. conorii* in the Mediterranean region, and *R. australis* (Queensland tick typhus) in Australia. In the past three decades, many other species of organisms have been recognized as pathogens in humans.

Based on their serological reactions, the *Rickettsia* species are divided into *spotted fever* and *typhus* groups. The outer membrane protein A (ompA) gene is observed in SFG unlike the typhus group of organisms.

The earliest description of Rocky mountain spotted fever (RMSF) dates as far back as 1873. Howard Taylor Ricketts (1871–1910) studied RMSF in the Bitterroot Valley of Montana. He died eventually of typhus fever in Mexico City. Hence, the genus *Rickettsia* is rightly named after him.

Spotted Fever in India

Megaw first observed spotted fever in India during the year 1917 in the foothills of the Himalayas. Reports of Indian tick typhus (ITT) fever have come from all over the country. Recent reports state that ITT is prevalent in many districts of Maharashtra, Karnataka, Tamil Nadu, Andhra Pradesh and Kerala. ITT is endemic in the rural part of these areas.

ETIOLOGY

Rickettsia spp. are the causative organisms of spotted fevers. These are Gram negative coccobacilli belonging to the family rickettsiaceae and order rickettsiales of alpha-proteobacteria. SFG of *Rickettsia* contains many human pathogens that are transmitted by tick bites. Approximately 25 different types of spotted fevers have been reported.

Rocky mountain spotted fever is caused by *R. rickettsii*. In Brazil, this fever is called as Brazillian spotted fever. Mediterranean spotted fever (MSF) which is also called as boutonneuse fever is caused by *R. conorii* subsp. *conorii*. Other subspecies of *R. conorii* cause Israeli spotted fever (*R. conorii* subsp. *israelensis*), Astrakhan spotted fever (*R. conorii* subsp. *caspia*) and Indian tick typhus (ITT) (*R. conorii* subsp. *indica*). *R. slovaca* and *R. raoultii* are the causative organisms for the illness called TIBOLA (tick-borne lymphadenopathy) and DEBONEL (Dermacentor-borne necrosis erythema lymphadenopathy). African tick-bite fever (*R. africae*), Japanese or Oriental spotted fever (*R. japonica*), Queensland tick typhus (*R. australis*) and Flinders island spotted fever (*R. honei*) are some of the other named spotted fevers. Some of the pathogenic members of the SFG rickettsiae are transmitted by other arthropods. *R. felis* causes a syndrome called as flea-borne spotted fever or cat-flea typhus. Rickettsialpox is caused by *R. akari* and it is transmitted by mites.

TRANSMISSION

Tick-Borne Spotted Fevers

Most of the SFG rickettsiae have ticks as their vectors (Fig. 1). These sustain the infection through transovarial route, i.e., the organisms

Figure 1 An adult female *Rhipicephalus sanguineus* (brown dog tick)
Source: Public health image library (PHIL), CDC, USA.

are transmitted from the infected ticks to their progeny. Transstadial passage of organisms is also described. The ticks inject organisms into their mammalian hosts that include the humans, by regurgitating the infected saliva while feeding. Dogs and rodents serve as reservoir hosts for these vectors. These reservoir vectors can themselves develop the disease and are important vehicles for bringing potentially infected vectors into environment shared by humans. At times, crushed tick's tissues, fluids or feces enter the human body through breaks in the skin—resulting in entry of the rickettsial organisms. Blood transfusion is yet another route through which these organisms can be transmitted from an infected person to the noninfected.

Flea-Born and Mite-Born Spotted Fevers

R. felis and *R. akari* are the SFG rickettsiae that is transmitted by arthropods other than ticks. *R. felis* is predominantly found in cat flea, *Ctenocephalides felis*, which is at present the only arthropod known to be a biological vector. *R. akari* is transmitted by mite.

PATHOPHYSIOLOGY

There are two ways through which the rickettsial organisms are inoculated into the dermis of the skin: one of these is through a direct bite from the tick and another one is when the feces of the infected fleas come in contact with the damaged skin of the victim. Once inside the blood stream, these bacteria infect the endothelium. Attachment to the host cell is thought to be the first step of rickettsial pathogenesis. The outer membrane proteins are thought to be the primary adhesins. The host cells consume the rickettsiae that are attached to their cell membrane through phagocytosis. Since the rickettsial organisms enter the cells that do not normally phagocytose the outer particle, it is postulated that these organisms have the ability to induce the process of phagocytosis in the host cells. Once inside the cell, it is observed that the rickettsiae quickly enter the cytoplasm after lysing the phagosome membrane. The rickettsial organisms of SFG rarely accumulate in large numbers within the host cells, and these do not cause their lysis. These stimulate polymerization of the actin tails derived from the host cell in order to escape. These polymerized actin tails propel them through cytoplasm and into the tips of membranous extrusions from which they emerge. Signs of cell membrane damage associated with influx of water are observed within the infected cells. Rickettsiae are known to proliferate on the endothelium of smaller blood vessels where they release cytokines leading to disintegration of the endothelium. It leads to fluid

leakage and platelet aggregation. Focal proliferation of monocytes and polymorphs leads to occlusive end-arteritis or microvasculitis. It results in micro-infarctions and *Typhus nodules of Wohlbach* that are typical of typhus fevers. This mode of cell injury and its sequelae are typically observed in brain, heart muscle, skeletal muscle, skin, liver, lungs and kidneys. Occlusion of the venous leading to gangrene of the extremities is also observed.

CLINICAL MANIFESTATIONS

In children incubation period varies from 2 days to 14 days with a mean of 7 days. However, it may extend up to 28 days. Quite often, history of exposure to tick bite or close contact with an infected pet is forthcoming. Many times, history of travel from an endemic spot and similar illness in family members is available. Severity of manifestations varies from a mild, self-limiting illness to a life-threatening disaster.

Initially, the illness appears to be nonspecific and patients present with fever, headache, anorexia, restlessness and muscle pains. Pain and tenderness in calf region is common in children. Nausea, vomiting and diarrhea are the common gastrointestinal symptoms. Abdominal pain is a frequent complaint earlier in disease. Skin rash is usually not present till the disease has progressed for 2–4 days. In as many as 44% of the patients, the typical triad of fever, headache and rash is observed. Core body temperature can exceed 40°C, and it can either remain elevated or fluctuate drastically. A severe and unremitting type of headache, often not responding to analgesics, is common. Rash is usually discrete to begin with blanching macules or maculopapular rashes which can be pale or rose-red are typically seen on the extremities like ankles, wrist, and lower limbs.

Later, rash spreads quickly to involve the entire body including palms and soles (**Fig. 2**). Rash becomes more petechial or hemorrhagic, sometimes with palpable purpura (**Fig. 3**) after several days. The petechiae may enlarge to become ecchymosis and necrotic (**Fig. 4**) in severe form of the disease. Even though severe vaso-occlusive disease secondary to rickettsial vasculitis and vessel thrombosis is rare, when it does take place, it can result in gangrene of the digits (**Fig. 4**), toes, earlobes (**Fig. 5**), and entire limbs. *Tache noire* refers to painless eschar which may be observed at the initial site of tick attachment, and it may be associated with regional lymphadenopathy. Edema over the dorsum of hand or foot, periorbital edema and generalized edema are sometimes seen and so are hepatosplenomegaly and generalized lymphadenopathy.

Neurological Involvement

The name typhus originated from the Greek word *typhos*, which means smoky and refers to the cloudy sensorium of patients with typhus and other life-threatening rickettsioses. Rickettsial

Figure 3 Palpable purpura over lower limbs

Figure 4 Necrotic rash with gangrene of digits

Figure 2 Petechial rash over palm

Figure 5 Gangrene on earlobe

encephalitis manifests first as confusion or lethargy, as the disease progresses, stupor or delirium, ataxia, coma, deafness and seizures are observed. Involvement of blood vessels contiguous to the cerebrospinal fluid leads to pleocytosis in one-third of patients, usually 10–100 cells/mm³ with predominance of lymphocytes and macrophages. However, occasionally, more than 100 cells/mm³ with polymorphonuclear predominance are observed. Coma or seizures may be associated with fatal outcome.

Pulmonary Involvement

The pulmonary microcirculation is heavily infected by *Rickettsia* in severely ill patients. The effect is ARDS. Interstitial pneumonitis and alveolar edema are the most severe manifestations.

Renal

At times, rickettsial disease presents as renal failure indicating adverse prognosis. Sometimes disseminated intravascular coagulation like syndrome, myocarditis, gangrene and hepatic failure are seen in spotted fever.

INDIAN TICK TYPHUS (*RICKETTSIA CONORII* SUBSP. *INDICA*)

Until Megaw put forth the view that tick typhus exists in India as a distinct entity, ITT used to be diagnosed as Rocky mountain spotted fever (RMSF) because of the similarity of clinical illness.

R. conorii, the bacterium was considered to be the cause of ITT. Subsequent serologic studies showed significant differences in antibody responses of patients of ITT with the ITT rickettsial and type strains of *R. conorii*. Recently, using molecular methods, it was demonstrated that these rickettsiae are closely related although differing, as reflected in antigenic variation. Zhu et al. have proposed recently that the causative agent of ITT is a subspecies of *R. conorii*, and it is different from the agent of MFS, designated *R. conorii* subsp. *indica*.

Indian tick typhus has various names in the local language: *Kan Kapaya disease* (gangrene of earlobe), *Motha Govar*, *Ghodya Govar* and *Bibtya*. ITT is prevalent in many districts of Maharashtra, Karnataka and Tamil Nadu. The tick is the reservoir of infection. Various tick genera (e.g., *Rhipicephalus*, *Ixodes*, *Boophilus*, *Haemaphysalis*) have been incriminated as vectors. Rickettsial organisms can also be transmitted to dogs, rodents and other animals which assist in maintaining the disease cycle, and these animals bring these dangerous pathogens near human beings. Clinical presentation of ITT is similar to that of RMSF with less severity. But recent Indian reports state that ITT has clinical features as severe as those of RMSF.

The rash in ITT is frequently purpuric and inoculation eschar at the bite site is unusual unlike RMSF. A nonpruritic macular rash is commonly seen initially on the wrist, forearms, ankles or scrotum. It can appear from the 2nd to 4th day. It quickly spreads to involve the palms or soles along with trunk and extremities. To begin with, the spot blanch when pressed, but later develop typical petechiae.

DIAGNOSIS

At present, an assay providing rapid confirmation of early rickettsial fever is not widely available. The decision to treat must be based on epidemiological and clinical data. It is not advisable to wait for confirmation by laboratory results.

Hematology

During early course of disease, the total leukocyte count can either be normal or below normal with marked shift to left. Leukocytosis is seen in 30% of the cases as the disease progresses. In about 60% of the cases, platelet counts are low.

Biochemistry

Hyponatremia and reduced albumin levels in the blood reflect increase in vascular permeability. Often, hepatic transaminase levels are increased.

Serology

Many serological tests are available for diagnosing rickettsial diseases. Microimmunofluorescence, immunoperoxidase assay, indirect hemagglutination, enzyme-linked immunosorbent assay, latex agglutination, dot blot immunoassay (including dip-stick test) and Weil-Felix (WF) test are some of these. Since these tests become positive 5–7 days after the onset of symptoms, they cannot be depended upon to initiate suitable therapy.

Weil-Felix Test

This is a heterophile antibody test which has the sharing of antigens between *Rickettsia* and *Proteus* as its basis. It shows agglutinins to *Proteus vulgaris* strain OX 19, OX 2, OX K. Most of the literature published in western world has discouraged using this test for diagnosing rickettsial infections. Even though poor sensitivity of WF test is well-documented, a good correlation is observed between the results of WF test and detection of IgM antibodies by an indirect immunofluorescence assay (IFA). WF test can at best be used as a screening test because it detects more cases than misdiagnosed ones and also when it is positive, it is reasonably specific. In spite of the drawbacks, WF test still serves as a useful and affordable diagnostic tool for laboratory diagnosis of rickettsial disease—especially in the resource-starved developing world. Chief criteria for diagnosis by WF test are either a fourfold rise in titer in paired sera or a single titer of more than 1:320. Dependence on WF test is accepted in those circumstances where definitive investigations are not available. However, like any other test, WF test must be interpreted in appropriate clinical context.

Immunofluorescence Assay

This test is regarded as the gold standard test for serodiagnosis of rickettsial disease and allows detection of IgG and IgM antibodies. IgM titer more than 1:640 suggests acute infection. IgM begins to appear at 5–10 days and peak levels are reached 3–4 weeks after the onset of symptoms. IgG levels of more than 1:254 indicate acute infection. IgG greater than 1:64 but less than or equal to 1:125 suggest previous infection. Chief drawbacks of IFA are that it is expensive and not widely available.

Enzyme-linked Immunosorbent Assay

This test was initially introduced for detection of antibodies against *R. prowazekii* and *R. typhi*. This test is not only highly sensitive but also reproducible, allowing the differentiation of IgM and IgG antibodies. This technique was also adapted to diagnose RMSF and scrub typhus.

PCR-based Detection

Detection of *Rickettsia* from tissues and blood of infected patients is the technique of choice for early diagnosis (within first week) before seroconversion.

Amplification of specific DNA by PCR provides a quick method for detecting rickettsial infections. Real-time PCR might offer additional advantages of speed, reproducibility and low risk for contamination. Western immunoblot assay can also be used for early diagnosis.

DIFFERENTIAL DIAGNOSIS

Spotted fevers can mimic meningococcemia, measles and enteroviral exanthemas. Typhoid fever, leptospiral infection,

parvoviral infection, scarlet fever, rubella, Kawasaki disease, toxic shock syndrome, thrombotic thrombocytopenia purpura (TTP), hemolytic uremic syndrome, Henoch-Schönlein purpura, acute abdomen, aseptic meningitis, hepatitis, dengue fever, infectious mononucleosis, drug reactions, malaria, tularemia, anthrax and other causes of pyrexia of unknown origin are also included in differential diagnosis.

TREATMENT

Prompt initiation of therapy with appropriate antibiotics prevents more severe form of disease and avoids mortality. Usually, treatment for spotted fevers is initiated without waiting for laboratory confirmation. Even though treatment is not always necessary for some spotted fevers (e.g., rickettsialpox), antibiotics may be administered to shorten the illness. Tetracycline and chloramphenicol are two time-tested drugs to effectively treat rickettsial infections in patients of all ages including children with spotted fevers. Doxycycline is the drug of choice in all age groups. Tetracycline and doxycycline may cause discoloration of teeth in children who are less than 8 years of age while chloramphenicol can rarely cause aplastic anemia. Doxycycline can be used safely in young children because tooth discoloration is dose dependent and children are unlikely to require multiple courses.

Recommended Treatment Regimens

- *Doxycycline*: 2.2 mg/kg BID PO or IV, maximum 200 mg/day.
- *Tetracycline*: 25–50 mg/kg/dose 6 hourly PO, maximum 2 g/day.
- *Chloramphenicol*: 50–100 mg/kg/day 6 hourly, maximum 3 g/day.

The therapy should be continued for a minimum of 5–7 days and for at least 3 days until the patient is afebrile in order to avoid relapse. It is observed that patients treated with these regimens tend to become afebrile within 48 hours. Thus a typical treatment regimen lasts for less than 10 days.

Supportive Care

Appropriate antimicrobial therapy will resolve most infections rapidly and do not require hospitalization or other supportive care. Occasionally, intensive care treatment is required for severely infected children. A special attention to hemodynamic status is necessary in severely sick children because iatrogenic pulmonary edema or cerebral edema frequently occurs due to diffuse microvascular injury to the lungs, meninges and brain. Prudent use of corticosteroids for meningoencephalitis has been advocated by some, even though no controlled trials have been conducted.

PREVENTION

No vaccines are available. Known tick infested areas should be avoided. Daily inspection of body for tick bites is particularly important. Disinfection of dogs will minimize the tick population. Health education of people about mode of transmission by ticks and means of personal protection is equally important. Prophylactic antibacterial therapy is not recommended because tetracycline and chloramphenicol are only rickettsiostatic. Such therapy not only delays the onset of illness but also results in confusing clinical

picture by prolonging the incubation period. Flea control on pets goes a long way in reducing the risk of flea-borne spotted fever.

PROGNOSIS

Delay in diagnosis and appropriate treatment are the chief factors influencing the severity of illness or death. The case fatality rate was 10% for children and 30% for adults before the advent of effective antimicrobial therapy. A delay in initiating therapy can lead to irreversible vascular or end-organ damage leading eventually to death.

IN A NUTSHELL

1. Except Antarctica, spotted fever disease is prevalent throughout the world, and it is named after different geographic areas. In India, it is known as Indian tick typhus.
2. Majority of spotted fevers are transmitted by ticks. Microvasculitis is the hallmark of rickettsial infection.
3. Patients coming from endemic area and with history of contact with pets like dogs and tick bite should be suspected to have rickettsial infection.
4. Classical triad of symptoms consists of fever, rash and headache (irritability in young children).
5. Clinical features include fever, rash extending over palms and soles, palpable purpura, necrotic rash, gangrene, eschar, lymphadenopathy, edema over the body, pain in the legs and hepatosplenomegaly.
6. Meningoencephalitis, interstitial pneumonitis, ARDS, acute renal failure, myocarditis and disseminated intravascular coagulation are some of the complications.
7. Till date, an assay providing rapid confirmation of early rickettsial disease is not widely available. Immunofluorescence assay (IFA) remains the gold standard test for serodiagnosis of rickettsial disease after 1 week.
8. The decision to treat must be based on epidemiological and clinical data. A delay in treatment while waiting for confirmation of laboratory results must be avoided.
9. Doxycycline and chloramphenicol are the two time-tested drugs recommended to effectively treat rickettsial infections of all ages including children.
10. No vaccines are available. Health education of people about mode of transmission by ticks and means of personal protection is equally important.

Chapter 34.3

Scrub Typhus

Veena R Parmar

Scrub typhus is a form of rickettsial disease caused by genera *Orientia*. It differs from *Rickettsia* as its cell wall is deficient in lipopolysaccharide, and it exhibits antigenic heterogeneity. Rodents and arthropods are the natural hosts and humans get infected through the vector.

EPIDEMIOLOGY

Scrub typhus is endemic in India, Nepal, China, Tibet, Pakistan, Sri Lanka, Russia, Afghanistan, Japan, South Korea, Indonesia and Taiwan, and Northern Australia. These geographical areas form the famous Tsutsugamushi triangle. In these endemic regions, at any given time around 3% of population might be infected. Recently epidemics of scrub typhus have been reported from northern, eastern and coastal regions of India.

Mainly adults who live or camp in the scrub vegetation areas are susceptible to infection, but any age and sex including children can be affected. Recurrent infections are known as the post infection immunity wanes off in 1–3 years.

ETIOLOGY

Scrub typhus is caused by the intracellular parasite *Orientia tsutsugamushi* a gram-negative proteobacterium of family Rickettsiaceae. It is no more included in genus *Rickettsia* but is classified in genus *Orientia*. The trombiculid mites are the natural hosts. Humans get infection through the bite by the infected larval stage of the trombiculid mite called chiggers. The infection is most common in rainy season from June through November as the mites lay eggs in this season. The trombiculid larvae act as vector as well as reservoir of infection via transovarial transmission to their progeny.

PATHOGENESIS

A papule appears at the site of bite, which later gets necrotic and forms an eschar. Regional lymphadenopathy develops and may be tender. *Orientia tsutsugamushi* invades and replicate within the human monocyte macrophages and endothelial cells and induce expression of a large number of genes such as: type I interferon, interferon-stimulated genes, inflammation-associated genes and apoptosis-related genes and release of inflammatory cytokines like tumor necrosis factor and interleukin-1 β are released. Perivasculitis of small blood vessels sets in. Subsequent to these changes, the local and systemic inflammation sets in thus resulting in multiorgan involvement and clinical presentation.

CLINICAL FEATURES

In children, the disease may vary from being mild to a severe form. A painless eschar develops at the site of bite in about 50% of primary and 30% of secondary infections. Although eschar is found commonly on the lower limbs, other body parts such as arms, neck and scrotal region can be affected especially in children. By the time fever starts, the eschar is fully developed.

The incubation period ranges from 6 days to 20 days and usually corresponds to the eschar stage. There after the constitutional symptoms like headache, anorexia, malaise and abrupt onset of fever (40–40.5°) with chills start. Nearly 40% have pain abdomen, and vomiting. A transient centripetal maculopapular rash appears

on the 5th to 8th day of fever in about 40% cases. Acute loss of hearing, pathognomonic of scrub typhus occurs in a few cases. Regional and generalized lymphadenopathy is found in 20–90% cases and hepatosplenomegaly in about half of the cases. Some patients may develop encephalitis, encephalomyelitis, neurological deficits, myocarditis, disseminated intravascular coagulation, acute kidney injury (AKI), atypical pneumonia and acute adult respiratory distress syndrome like picture in the severe form of disease. The complication rate is less in children but higher in patients above 60 years of age, especially in those with leukocytosis above 10,000/ μ L, or eschar. The symptoms resolve within 36–48 hours with specific and supportive treatment but may last for 2 weeks if left untreated. High levels of Interleukin-8 are associated with a higher disease severity and mortality.

DIAGNOSIS

Scrub typhus should be suspected and excluded in all patients presenting with high-grade fever, rash, lymphadenopathy and renal failure. Presence of eschar and acute hearing loss is pathognomonic. History of visit to endemic areas should be elicited. The diagnosis can be confirmed with serological and other tests as follows. Presence of a combination of leukocytosis, transaminitis and thrombocytopenia in a febrile child with or without eschar coming from an endemic area should alert one to the diagnosis.

The Weil–Felix agglutination test, though not very sensitive and specific but cost effective is still being used. It becomes positive after 5th to 10th day of onset of illness in about 50–70% cases. A fourfold or higher rise in titer to *proteus* OX-K and no reaction to *proteus* OX-2 or OX-19 or a single titer greater than or equal to 1:160 is diagnostic.

Enzyme-linked immunosorbent assay (ELISA); the 56-kDa protein is located on the outer membrane of *O. tsutsugamushi* is highly reactive with patient sera; the trivalent ELISA using whole cell antigen and r56 from the Karp, Kato, and Gilliam strains of *O. tsutsugamushi* (KpKtGm-wc ELISA and KpKtGm r56) is highly sensitive and specific but expensive.

Indirect fluorescent assay is a more sensitive and gold standard test for scrub typhus but is costly. A fourfold rise in antibodies in paired sera is diagnostic. Specific IgM antibodies can also be demonstrated with the indirect immunochromatographic test, which is rapid and highly sensitive and specific.

Polymerase chain reaction (PCR) is a very sensitive test for the detection of *O. tsutsugamushi*. Apart from blood, it can also be performed on the tissue from eschar. The organisms can be detected within 1–3 days of onset of fever by nested PCR which is 100 times more sensitive but expensive than single PCR. *O. tsutsugamushi* can be isolated and cultured from a patient's blood by inoculating it intraperitoneal, into white mice or Guinea pig but is still carried out only in research laboratories.

Early lymphopenia with late lymphocytosis, a decrease in the CD4:CD8 lymphocyte ratio and thrombocytopenia is seen in 75–95% of patients. Transaminase levels may be raised and hypoalbuminemia occurs in about 50% of cases, more so in children. Hyperbilirubinemia is rare. X-ray of chest shows pneumonitis, especially in the lower lung fields. Histologically, focal or disseminated vasculitis and the perivascular infiltration of leukocytes can be seen.

TREATMENT

To reduce the morbidity and mortality, specific and supportive treatment must be initiated early in the course of the disease on the basis of a presumptive diagnosis. Scrub typhus patients respond more promptly and fever resolves within 24–36 hours. Relapses

Table 1 Drug treatment of scrub typhus

Drug	Route and dosage	Duration
Doxycycline or	4 mg/kg/day PO/IV divided q 12 hours x 1 day <i>Maintenance:</i> 2.2–4.4 mg/kg/day IV/PO divided BID for 5–7 days or 3 days after fever subsides (whichever is longer)	5–7 days or afebrile for > 3 days
Tetracycline	25–50 mg/kg/day, maximum 2 g/day PO in 6 hourly divided dosages	
Chloramphenicol	50–100 mg/kg/day IV divided every 6 hours, maximum 4 g/day	5–7 days or afebrile for > 3 days
Azithromycin*	≥ 6 months: 10 mg/maximum 200 mg/day/kg PO on day 1, followed by 5 mg/kg PO on days 2–5	5 days
Rifampicin*	10–20 mg/kg/day IV/PO or 10–20 mg/kg PO twice weekly (DOT); not to exceed 600 mg/day	

*More effective in doxycycline resistant cases. (Reported recently from Thailand)

may occur if the antibiotics are not taken for a long enough period. Drug therapy is shown in **Table 1**.

Supportive measures such as maintenance of fluid and electrolyte balance, prompt and aggressive treatment of shock, maintenance of nutrition, respiratory support, etc. should be provided as per need.

PROGNOSIS

Patients develop serious complications and may even die if treatment is delayed. Mortality ranges from 1% to 60%, depending on the geographic area and the pathogenic strain. Death can occur either from the primary infection or from secondary complications (e.g., pneumonitis, encephalitis, or circulatory failure, acute renal failure, etc.). Most fatalities occur by the end of the second week of infection.

PREVENTION

Achieve adequate vector control by use of insecticides and clearing of scrub vegetation from the camping sites. Bites by chiggers can be minimized by wearing protective clothes and using insect repellents. No effective vaccine against scrub typhus is available currently.

Chemoprophylaxis Doxycycline and chloramphenicol have been tried with variable results. A single dose of doxycycline is given weekly; start before exposure and continue for 6 weeks after exposure. Or a single dose of chloramphenicol or tetracycline given orally once every 5 days for a total of 35 days.

IN A NUTSHELL

1. Scrub typhus is endemic to India and children also can be affected.
2. Scrub typhus is caused by rickettsia *tsutsugamushi* species of genera *Orientia*. The infection occurs through the bite of infected larval stage of the trombiculid mite called chiggers.
3. Clinically the disease presents as acute febrile illness with lymphadenopathy, rash and other systemic features in more severe forms, particularly acute renal failure. Eschar at the site of bite is pathognomonic.
4. High suspicion index for the disease is helpful in early diagnosis and treatment.
5. Diagnosis can be confirmed by immunological tests.
6. Tetracyclines (doxycyclines) are the drug of choice.
7. Adequate vector control is helpful in prevention.

Chapter 34.4

Epidemic Typhus

Sunil Vaidya, Atul A Kulkarni

Epidemic typhus is a lethal exanthematous disease caused by *Rickettsia prowazekii* and is transmitted by the human louse. Typhus was also known as *Jail Fever*, as it was common in prisons. At present, epidemic typhus is considered as a potential bioterrorism agent (category B, CDC). It may be a serious threat in disaster struck areas of the world, where unhealthy living conditions and social disturbances prevail and the population is prone for louse infestations.

HISTORICAL ASPECTS

The first historical evidence of typhus comes from an outbreak in a Sicily Monastery in 11th century. It then spread throughout the entire Europe in 16th–19th century. These epidemics were described in many wars including the English Civil War (1642–1651), the Thirty Years' War (1618–1648), the Napoleon Wars (1803–1815). During 1618–1648, different kinds of pests related illness, mainly typhus surged in Germany and surrounding nations. In the famous retreat from Russia by Napoleon, more French soldiers died due to typhus than they were killed in war. Typhus epidemics reached the peak in Russia in 1922, when an enormous number of 25–30 million cases and 3 million deaths were reported.

In the year 1928, Charles Nicolle won the Nobel Prize in Medicine for identifying louse as the transmitter of epidemic typhus. In 1948, Paul Hermann Müller, discovered DDT as a highly efficient contact poison against the lice and several arthropods, and was awarded the Nobel Prize for his revolutionary research.

Typhus spread through Europe, North Africa, and the Pacific Islands in the 20th century. As reported by Byrne, by the end of war typhus accounted for more than 10% deaths of the total German population and the disease lead to 90% of deaths in Europe.

TRANSMISSION

Rickettsia prowazekii is the causative organism for epidemic typhus and is carried by body lice. During the feed of lice on a human body, they also defecate. On the scratch of the bite, the feces containing the organisms are inoculated into the wound. Body lice are commonly seen in people who live under cold, overcrowded, dirty conditions, without any opportunities to wash themselves or their clothing.

The reactivation of an earlier infection with epidemic typhus leads to a relatively mild illness and is termed as Brill–Zinsser disease. It affects people years after they have completely recovered from epidemic typhus. The bacteria are reactivated as a result of weakening of immune system, as it occurs in old age, surgery, major illness, etc.

EPIDEMIOLOGY

Epidemic typhus is commonly seen in communities affected by poverty, war, natural calamities like flood, earthquakes and in populations like prisoners, refugee camps, where body lice are easily transmitted and prevalent. Outbreaks are often reported during cold climate as infested clothing is not laundered. Visitors are at risk for epidemic typhus who work with or visit such infested areas.

In India, the reported numbers may be quite less due to non-availability of confirmatory laboratory tests, failure to diagnose

the disease, lack of reporting and inadequate records. However, rickettsial disease in India has been reported in sub-Himalayan populations from Jammu and Kashmir, Himachal Pradesh, also from Uttaranchal and West Bengal.

CLINICAL FEATURES

Many children with fever and maculopapular rash in routine practice are often labeled as viral fever or viral exanthematous fever. With high index of suspicion, typhus or rickettsial infection can be diagnosed earlier. Rickettsioses are difficult to diagnose specifically to their subtypes. The clinical presentations vary with each patient and causative rickettsial subtypes. Within 1–2 weeks of infection, common symptoms like fever, headache, weakness, and muscle aches develop. Maculopapular rash may be present in 10–30% of the patients. The rash starts on the back, chest and abdomen, further spreads to the arms and legs.

Epidemic typhus manifest one or more abnormalities of function of the CNS, such as signs of meningeal irritation or signs of focal or generalized neurological involvement like seizures, hearing loss, confusion, drowsiness and coma. Myocarditis, pulmonary involvement (interstitial pneumonitis, bronchitis, or bronchiolitis), thrombocytopenia, jaundice, and abnormal liver function tests may be noted in severe cases. Brill–Zinsser disease is a mild illness with prolonged fever, and a light rash. Most symptomatic rickettsial diseases cause moderate illness, but epidemic typhus and rocky mountain spotted fever can be severe and may be fatal if untreated.

DIAGNOSIS

The clinical findings itself are diagnostic. Fever, headaches, evidence of scratching and skin rash are the usual symptoms which should arouse the suspicion. Circumstantial evidence like unhygienic patients infested with body lice, overcrowding, lack of cleaning facilities as in slum areas are supportive. Thrombocytopenia and an increase of the hepatic enzymes can be observed especially in severe cases. *R. prowazekii* cannot be grown on artificial media and specialized laboratory facilities are required to recover the organism. Diagnosis is usually done clinically and supported by serological investigations. The microimmunofluorescence antibody test is the standard test for the diagnosis of rickettsial disease. It can indicate acute and old infections by IgM generally identified and IgG antibody responses. Causative organism can be specifically identified by serologic testing. In advanced facilities, immunohistochemical analysis and PCR can be helpful.

TREATMENT

Treatment of patients with clinically suspected rickettsial infection should be started immediately and should not await for laboratory confirmation. Doxycycline, chloramphenicol and azithromycin are mainstay of the treatment. Doxycycline is the drug of choice and given in dose of 5 mg/kg/day. Oral treatment is preferred unless patient is vomiting, drowsy or comatose. Therapy should be given for at least 3 days after patient becomes afebrile, or for total 5–7 days. Majority of treated patients improve markedly within 48 hours after initiation of therapy.

PREVENTION AND CONTROL

Delousing is the most important preventive measure for this infection and has been the turning point in controlling the epidemics of typhus. As body lice and their eggs are present in

the clothes, removal and destruction or washing and boiling of all clothes can effectively destroy lice. Application of all clothing with DDT, malathion, permethrin (as in the WHO protocol) is also effective method of killing body lice and reducing re-infestation. Although protective vaccines have been developed, they have not been widely used because effective antibiotic treatments are readily available.

- Frieden IJ, Resnick SD. Childhood exanthems—old and new. *Pediatr Clin N Am.* 1991;38:859-87.
- Raoult D, Parola P. *Rickettsial Diseases*. New York: Informa Healthcare USA, Inc; 2007.
- Rathi N, Rathi A. Rickettsial infections: Indian perspective. *Indian Pediatr.* 2010; 47:157-64.

IN A NUTSHELL

1. Epidemic typhus (caused by *R. prowazekii* and transmitted by lice) is more of historical importance although resurgence is noted in 1997, so instituting hygienic methods and prevention of lice infestation is important.
2. War, famine, refugee camp and jail have reported epidemics of typhus fever.
3. Rickettsial infections are difficult to diagnose and high index of suspicion is essential for early diagnosis and treatment.
4. Fever, maculopapular, hemorrhagic rash, headache, myalgia are initial features of these infections.
5. Therapy should be started at the earliest even with clinical suspicion to avoid morbidity and mortality.
6. Treatment is cheap, affordable and the response to therapy is dramatic. Doxycycline is the drug of choice, and it can be used safely in children.

Chapter 34.5

Murine Typhus (Endemic Typhus)

Govind Benakatti, LH Bidari

Murine typhus, also known as *endemic typhus*, or *flea borne typhus*, is an important cause of acute febrile illness; and is most widely distributed flea borne rickettsial infection worldwide. It is caused by *Rickettsia typhi* and transmitted by infected fleas. Due to lack of awareness, it is the most under-recognized and under-reported illness worldwide. In areas, where febrile illnesses are common, studies have shown that incidence of murine typhus ranges from 0.5% to 6% in various countries. Murine typhus and epidemic typhus (caused by *R. prowazekii*) belong to typhus group rickettsial illnesses. Genomics of *R. typhi* and *R. prowazekii* have similar structures and share similar clinical characteristics, but murine typhus is considered as milder spectrum of disease with favorable prognosis. There are no published literatures from India on this condition.

EPIDEMIOLOGY

R. typhi is primarily transmitted by rat flea *Xenopsylla cheopis* and maintained in rat-flea-rat cycle where rats act as the main reservoirs. Murine typhus is distributed worldwide, largely in tropical and subtropical regions (ports and coastal areas) involving urban environment where high population of rats and domestic rodents are found. Though rat fleas are the primary vectors of transmission, lice and mites also act as potential vectors. Other vertebrate hosts such as house mice, shrews, opossums, skunks, and cats are the reservoirs. Rat and rat fleas do not suffer disease and remain infected lifelong. Murine typhus often follows a seasonal distribution and transmission rate correlates closely with population of rat fleas. Peak incidence of murine typhus occurs around spring and summer in urban areas and fall in coastal areas when fleas are most abundant. Though murine typhus is an endemic illness, outbreaks have been described in literature. It is also been recognized as an important cause of travel acquired rickettsial fever with Africa and Southeast Asia being the most frequent sites of disease acquisition.

ETIOLOGY

R. typhi is transmitted by inoculation of infected flea feces at the bite site and gains entry into the host through contamination of infected site which is facilitated by rubbing or scratching of bite site. When blood feeding fleas feed on the infected reservoir, organism gains entry into the midgut of fleas where they invade and multiply within the gut epithelium. This multiplication eventually leads to rupture of these cells and release large number of rickettsiae into the gut lumen. This process usually takes 3–4 days before recognizable number of rickettsiae can be seen in feces and become the source of infection to the human and other mammalian hosts. Typically fleas become infectious approximately 10 days after they get infected and remain infectious throughout rest of their life.

PATHOGENESIS

R. typhi is a vasculotropic obligate intracellular pathogen just like other rickettsiae. Endothelial cells are the primary target cells and widespread endothelial injury with increased vascular permeability is the hallmark pathophysiologic feature of rickettsial infections. The diversity of microvascular injury explains the wide

spectrum of clinical manifestations. In contrast to other rickettsiae, *R. typhi* has limited intracellular mobility that explains the less severe manifestations of murine typhus.

CLINICAL FEATURES

The incubation period is 7–14 days with average being 10 days. The initial manifestations of murine typhus are often nonspecific with prodromal symptoms of headache, joint pains and persistent fever. Often it presents as *fever without focus* that usually lasts for 3–7 days followed by onset of rash that begins on trunk and spread peripherally. Though rash is the hallmark diagnostic feature of rickettsial diseases, its presence in murine typhus varies from 20% to 80% of cases and absence of rash should not preclude the diagnosis of murine typhus. The characteristics of rash in murine typhus are similar to that in other rickettsial infections as being nonpruritic, macular or maculopapular starting on the trunk and then spreading peripherally, can involve both palms and soles; lasting 1–4 days; and occurring, on an average 1 week after the onset of fever. Less than half (up to 40%) of patients reported to have flea bite site evident on examination. Severe manifestations such as meningoencephalitis, stupor, coma, seizures, hepatitis, myocarditis, endocarditis, multiorgan dysfunction, etc. though less common have been reported. The most common laboratory abnormalities include anemia (18–75%), leukopenia (18–40%), leukocytosis (1–29%), thrombocytopenia (19–48%), elevated ESR (59–89%), and elevated aminotransferase levels (38%–90%), hyponatremia (20–66%), and hypoalbuminemia in 46–89%.

DIAGNOSIS

Differential Diagnoses

Due to its wide spectrum of manifestations and as it most commonly presents as fever of unknown origin; high index of suspicion is needed to diagnose murine typhus at the outset of presentation to the hospital. It is often difficult to distinguish murine typhus from other rickettsioses such as Rocky Mountain spotted fever and scrub typhus. Thus murine typhus should always be considered as a differential diagnosis of fever without focus, and those with fever with maculopapular rash. Differential diagnosis include common causes of fever of unknown origin such as enteric fever, bacteremia, and viral pyrexia and fever with rash such as viral exanthems, rubella, measles, infectious mononucleosis, roseola, and Kawasaki disease, etc. All differential diagnoses discussed in previous two chapters for these illnesses also apply here.

Laboratory Diagnosis

Though many laboratory methods are available; diagnosis and treatment of murine typhus is primarily made on clinical basis. Laboratory diagnosis is sought often for the confirmation of diagnosis. Currently indirect fluorescent antibody test is considered as *gold standard* and most widely used. A titer of more than or equal to 1:64 at the end of first week is considered as diagnostic with sensitivity of 94–100% and specificity of 100%. EIA to detect IgM has sensitivity of 88% and a specificity of 91%. Though Weil–Felix (based on principle of heterophile agglutination with *Proteus* spp.) test has very poor sensitivity and specificity is still the most widely used test in India for diagnosis of rickettsial infection. Murine typhus patient's sera react with OX-19. Other available tests include PCR and serologic assays such as indirect immunoperoxidase assay, latex agglutination and Western blot.

MANAGEMENT

Doxycycline is the treatment of choice (4 mg/kg/day divided 12 hourly PO or IV, maximum 200 mg/day). Effective alternative include; chloramphenicol (50–100 mg/kg/day divided every

6 hours, maximum 4 g/day). Quinolones (ciprofloxacin, ofloxacin) are also effective but associated with higher relapse rate. Macrolides (azithromycin, clarithromycin) are effective alternatives. Therapy is continued minimum of 5 days (usually 3–7 days) or at least 48 hours following defervescence.

PROGNOSTIC FACTORS

Murine typhus is usually considered as a benign self-limiting disease with mortality rate of 1%. It has excellent prognosis provided appropriate antibiotics are used. Delay in diagnosis and treatment is the single most important prognostic factor. However, 5–10% of children do suffer from severe illness such as meningoencephalitis, seizures, coma and multiorgan dysfunction requiring intensive care unit admission. All organ supportive therapy along with strict hemodynamic monitoring and careful fluid management is mandatory to avoid adverse outcome.

PREVENTION

Murine typhus infection can be effectively prevented through flea control measures on pets, especially domesticated cats. Currently no vaccine is available against murine typhus, and it is not known whether infection confers lifelong immunity.

- Gikas A, Doukakis S, Padiaditis J, et al. Comparison of the effectiveness of five different antibiotic regimens on infection with *Rickettsia typhi*: therapeutic data from 87 cases. *Am J Trop Med Hyg*. 2004;70:576-9.

Gikas A, Doukakis S, Padiaditis J, et al. Murine typhus in Greece: epidemiological, clinical and therapeutic data from 83 cases. *Trans R Soc Trop Med Hyg*. 2002;96:250-3.

Raby E, Dyer JR. Endemic (murine) typhus in returned travelers from Asia, a case series: clues to early diagnosis and comparison with dengue. *Am J Trop Med Hyg*. 2013;88:701-3.

IN A NUTSHELL

1. Murine typhus (endemic typhus) is one of the most under reported illness distributed worldwide especially in tropical, subtropical regions and coastal ports.
2. *Rickettsia typhi* (causative agent of murine typhus) shares similar genomes and clinical characteristics with *R. prowazekii* (causative agent of epidemic typhus) but is a much less severe form of illness.
3. Although rash is the hallmark diagnostic feature of the rickettsial illnesses, most common initial presentations of murine are nonspecific, and most commonly, it presents as fever without focus. Therefore, it should be considered in the list of differential diagnosis of all common causes of fever of unknown origin.
4. Murine typhus is considered as self-limiting infection with excellent prognosis. Mortality rate is about 1% provided appropriate antibiotics are used. However 5–10% children can have severe manifestations such as meningoencephalitis, splenic rupture, persistent abdominal pain, and endocarditis.
5. Doxycycline is the treatment of choice with chloramphenicol, azithromycin, clarithromycin being the effective alternatives.

Chapter 34.6

Mycoplasma Infections

Tanu Singhal

Mycoplasma are the smallest of free-living life forms with characteristics somewhere between bacteria and viruses. They measure 150–250 nm and lack cell walls, have sterols in the cell membrane, contain both RNA and DNA, have fastidious growth requirements but can grow in cell-free media (**Fig. 1**). The most important species causing human disease is *Mycoplasma pneumoniae*. The genital *Mycoplasmas* (*M. hominis* and *Ureaplasma urealyticum*) are associated with genital tract disease in adults and sometimes neonatal disease.

EPIDEMIOLOGY

Disease due to *Mycoplasma* is prevalent worldwide and occurs in all seasons. It is transmitted from person to person as a droplet infection and hence community, school and family outbreaks are not uncommon. Outbreaks in schools have been attributed to poor ventilation. Newborns can get infected by genital *Mycoplasmas* during delivery. *M. pneumoniae* can infect children of any age but is uncommon in the first year of life. Children less than 3 years usually suffer from an upper respiratory tract infection. The rates of infection and incidence of lower respiratory disease rise with increasing age especially in school-aged children and adolescents where it cause more than one-third of all community-acquired pneumonias (CAP). Children with humoral immunodeficiency, congenital heart disease, Down syndrome and sickle cell disease are likely to have severe and complicated illness.

PATHOGENESIS

Mycoplasma causes infection by attaching to the ciliated and nonciliated epithelium of the respiratory and genital tracts. The attachment protein is a complex carbohydrate similar to the I antigen of the red blood cells. Antibody response to this receptor causes the formation of the I antibody, a cold agglutinin that acts as an autoantibody. Following attachment, *Mycoplasma* causes damage by direct cytolysis or immune-mediated reaction. Systemic spread of *Mycoplasma* does not occur and the extrapulmonary manifestations are due to an immune-mediated mechanism.

Figure 1 Fried-egg colonies of *Mycoplasma* on agar media

CLINICAL FEATURES

The most common manifestations of *Mycoplasma* disease are low-grade fever, cough, headache, malaise, pharyngitis, rhinorrhea and sometimes otitis media. Bullous myringitis is a classic but rare manifestation of *Mycoplasma* infection. Wheezing is common especially in asthmatic children. Acute asthma may be the first presenting manifestation. The cough is insidious in onset, worsens over the next few days and can be quite debilitating. Only a minority of the infected children (especially those who are older), suffer from lower respiratory disease and pneumonia. Tracheobronchitis and bronchopneumonia are the most frequently reported severe manifestations. Pneumonia is associated with few clinical signs and is of varying severity. Patients rarely appear ill and hence the term *walking pneumonia*. There is marked disparity between the clinical symptoms and signs and the radiographic picture. The radiographic picture is variable; the most common finding is thickened bronchial shadow, streaks of interstitial infiltration, and areas of atelectasis primarily in lower lobes. There may be hilar adenopathy and pleural effusion. In some children, fulminant pneumonia and respiratory failure may occur.

Extrapulmonary manifestations can coexist/follow/occur independently of respiratory disease. The commonest extrapulmonary manifestations are dermatologic and include an erythematous macular and/or morbilliform rash or a papulovesicular exanthem or erythema nodosum. In some patients, erythema multiforme or Stevens-Johnson syndrome may occur. *Neurologic manifestations* include encephalitis, aseptic meningitis, transverse myelitis, peripheral neuropathies and radiculopathies, brainstem dysfunction, dysfunction of the pyramidal or extrapyramidal tract, cerebellar dysfunction, cerebral infarction and Guillain-Barré syndrome. *Mycoplasma* should be suspected as a cause of acute febrile encephalopathy especially if there are preceding or coexistent respiratory manifestations. Cold antibody mediated immune *hemolytic anemia* is another complication which may be vary from subclinical hemolysis to life-threatening hemolytic anemia. Rarely the gastrointestinal tract (GIT), heart, kidneys and joints may be involved. Neonates with genital *Mycoplasma* infection may present with cough/wheezing or sepsis, meningitis and brain abscess.

DIFFERENTIAL DIAGNOSIS

Respiratory *Mycoplasma* infections should be differentiated from pneumococcal and respiratory viral infections (influenza, parainfluenza, adenovirus, respiratory syncytial viral infections) and other atypical pneumonias. Central nervous system (CNS) *Mycoplasma* infections should be differentiated from other causes of acute febrile encephalopathy.

DIAGNOSIS

Complete blood count shows anemia, leukocytosis with neutrophilia and elevated erythrocyte sedimentation rate (ESR). Liver transaminases can be mildly elevated. In CNS disease, there is lymphocytic pleocytosis, elevated protein and normal glucose in the cerebrospinal fluid (CSF). The peripheral smear may show rouleaux formation due to the cold agglutinins and may be a pointer towards diagnosis (**Fig. 2**). Incubating the serum of the patient with type O erythrocytes at 4°C and observing for agglutination that reverses at 37°C indicates the presence of cold agglutinins. The sensitivity and specificity of cold agglutinins in *Mycoplasma* disease is around 50%. Higher the cold agglutinin titer, higher is the specificity.

Specific diagnosis is possible by demonstration of anti-*Mycoplasma* immunoglobulin M (IgM) by enzyme-linked immunosorbent assay (ELISA). IgM antibodies appear usually 7 days after infection and may be negative in early disease. They remain elevated for a long-time. *Mycoplasma*-specific polymerase chain

Figure 2 Peripheral smear showing red cell agglutination in *Mycoplasma* disease

reaction (PCR) from respiratory secretions is very sensitive and specific but expensive and not easily available. Most multiplex PCR kits for diagnosis of respiratory infections include *Mycoplasma* PCR.

TREATMENT

Respiratory Disease

Empirical therapy for *Mycoplasma* is recommended for all children especially those above 5 years with CAP where clinical features suggest *Mycoplasma*/atypical pathogens and in those children with CAP who do not respond to beta-lactam drugs. In children especially those more than 5 years with severe or very severe disease, empirical therapy with macrolides at the outset may be considered irrespective of clinical features. Treatment of acute asthma exacerbations with macrolides in view of the relationship between *Mycoplasma* and wheezing has no demonstrable benefit.

Since *Mycoplasmas* lack cell walls, all cell wall active antibiotics including beta-lactams are inactive. Macrolides are the drugs of choice for *Mycoplasma*. Recommended regimens include azithromycin 10 mg/kg in one dose on the first day and 5 mg/kg in one dose for 4 days, clarithromycin 15 mg/kg/day in two divided doses for 10 days, or erythromycin 30–40 mg/kg/day in four divided doses for 10 days. Azithromycin and clarithromycin have the advantages of less frequent dosing and fewer gastrointestinal disturbances.

In children older than 8 years, tetracycline 20–50 mg/kg/day in four divided doses (maximum daily dose 1–2 g) or doxycycline 2–4 mg/kg/day in one or two divided doses (maximum daily dose 100–200 mg) for 10 days also is effective.

M. pneumoniae resistant to macrolides has been reported from various countries. Prolonged fevers may occur in children with macrolide-resistant isolates who are treated with macrolide antibiotics. The possibility of macrolide resistance should be considered in children with suspected *M. pneumoniae* infection who do not respond as expected to macrolide therapy. Tetracyclines in doses detailed above and fluoroquinolones (e.g., levofloxacin) are alternative treatments for macrolide-resistant strains. Fluoroquinolones should only be used in children younger than 18 years if the benefits of therapy exceed the risks. Information regarding levofloxacin dose in children is limited.

Extrapulmonary Disease

Mycoplasma should be considered as a cause of acute febrile encephalopathy/encephalitis in children especially if there

is a coexisting or preceding respiratory illness. The role of antimicrobials is uncertain as pathology appears to be immune-mediated treatment modalities of uncertain efficacy that have been used in this setting include antimicrobials, steroids, diuretics, anti-inflammatory drugs, intravenous immunoglobulin (IVIG) and plasma exchange. Antimicrobials with good CNS penetration like fluoroquinolones and chloramphenicol may be considered. Severe hemolytic anemia has been treated with warming, steroids and plasma exchange. *Mycoplasma* should be suspected as a cause of neonatal sepsis in a setting of nonresponse to standard antibiotics in neonatal sepsis/respiratory disease.

PROGNOSIS

The outcome of pulmonary disease is generally good; no accurate data is however available. Acute complications include necrotizing pneumonia, acute respiratory distress syndrome (ARDS) and long-term complications include possible predisposition to recurrent wheezing and reduced lung function. Most cases with CNS complications recover though mortality and long-term sequelae may occur.

IN A NUTSHELL

1. *Mycoplasma* is a common cause of lower respiratory illness in older children and adolescents.
2. Specific diagnosis of disease on the basis of clinical manifestations is difficult. Laboratory diagnosis can be attempted by detection of specific IgM antibodies by ELISA.
3. Empirical therapy for *Mycoplasma* with macrolides should be considered in older children/adolescents with CAP not responding to beta-lactam antibiotics or at the outset in severe disease.
4. Corticosteroids are used in the therapy of severe disease particularly in CNS complications.

Chapter 34.7

Chlamydial Infections

Sulochana Putali Bai

Chlamydia are obligate intracellular bacterial pathogens whose entry into mucosal epithelial cells is required for their intracellular survival and growth. It causes a variety of diseases in animal species like birds, reptiles and mammals. The most common human pathogens are *Chlamydia pneumoniae* and *Chlamydia trachomatis*.

MICROBIOLOGY

The family Chlamydiaceae consists of two genera: *Chlamydia* and *Chlamydophila*. One species of *Chlamydia* and two of *Chlamydophila* are important in causing disease in humans.

- *Chlamydia trachomatis* can cause urogenital infections, trachoma, conjunctivitis, pneumonia and lymphogranuloma venereum (LGV).
- *Chlamydophila pneumoniae* can cause bronchitis, sinusitis, pneumonia and possibly atherosclerosis.
- *Chlamydophila psittaci* can cause pneumonia (psittacosis).

Members of the Chlamydiaceae are small obligate intracellular bacteria. They depend on the host cell for ATP as they are unable to produce them. Their inner and outer membranes are similar to gram-negative bacteria and the membrane contains lipopolysaccharide but does not have a peptidoglycan layer. *Chlamydia* are susceptible to antibiotics that interfere with DNA and protein synthesis, including tetracyclines, macrolides and quinolones. *Chlamydia* exists in two distinct morphological forms:

1. Elementary body (EB) which is the infectious form. EBs are small (0.3–0.4 μm) and possess a rigid outer membrane that is extensively cross-linked by disulfide bonds. They are considered similar to spores because they are metabolically inactive and due to their rigid outer membrane, the elementary bodies are resistant to harsh environmental conditions outside their eukaryotic host cells. The elementary bodies bind to receptors on host cells (epithelial cells) and initiate infection.
2. Reticulate body (RB) which is the reproductive form. RBs are the noninfectious intracellular form of the *Chlamydia*. They are different from the EBs as they are metabolically active replicating form of the *Chlamydia* and they possess a membrane which lacks extensive disulfide bonds.

PATHOGENESIS

During chlamydial infection, the infectious EBs attaches to the host cell and are internalized by endocytosis and/or by phagocytosis. EBs remain within a phagosome by inhibiting phagosomal lysosomal fusion. The complete intracellular life cycle of the *Chlamydia* occurs within the phagosome. The EB transforms into a RB, within 8 hours and RBs begin to multiply by binary fission within an isolated area called an inclusion. After approximately 36 hours, the RBs differentiate back into EBs. The inclusion may contain 100–500 EBs per inclusion. After 48 hours EBs are released by exocytosis (extrusion of whole inclusion in *C. trachomatis* and *C. pneumoniae*) leaving the host cell intact or by cytolysis (*C. psittaci*).

Chlamydia may enter into a persistent state after treatment with IFN- γ or penicillin and due to lack of certain nutrients. It shows decreased metabolic activity, loss of infectivity, small inclusions with less numbers of EBs (altered inclusions) and refraction to

antibiotic treatment during the persistent state. *Chlamydia* have been shown to modulate cellular apoptosis (induce or inhibit based on the stage of developmental cycle) for their survival and replication. *Chlamydia* protects infected cells against apoptosis during initial stages of infection and induces apoptosis of host cell during final stages of the developmental cycle. The altered inclusions and inhibition of apoptosis may be the mechanisms of persistent infection.

CHLAMYDOPHILA PNEUMONIAE INFECTION

Chlamydophila pneumoniae (formerly known as *C. pneumoniae*) is a human respiratory pathogen associated with otitis media, sinusitis, bronchitis, pneumonia, pharyngitis, chronic obstructive pulmonary disease, asthma and atherosclerosis.

Epidemiology

C. pneumoniae is distributed worldwide. The prevalence increases with age; the seroprevalence rate sharply increases between 5 years and 20 years reaching more than 70% in adults. Reinfection is highly common even with such high prevalence. The organism is transmitted from human to human by infected respiratory secretions. It commonly spreads within families and enclosed population.

Pathophysiology

Acute infection of the lung due to *C. pneumoniae* causes acute patchy pneumonia with infiltrates in the alveoli and interstitial tissue of the lung. It is characterized by alveolar edema and mononuclear infiltrate. Reinfection by *C. pneumoniae* is common and characterized by interstitial pneumonia. In certain pneumonia cases, *C. pneumoniae* may not be the primary pathogen but its infection may have disrupted the normal clearance mechanisms and would have enabled other respiratory pathogens, like pneumococci to invade and cause pneumonia.

Clinical Features

Most *C. pneumoniae* infections are mild and asymptomatic but in few cases it has been fatal. In symptomatic infection the onset is gradual and presents initially with fever and pharyngitis which develops into cough and pneumonia over a week. Wheeze and crackles may be present resembling viral associated wheeze. It is one of the causes of atypical pneumonia resembling *Mycoplasma pneumoniae*. Clinically pneumonia due to *C. pneumoniae* is indistinguishable from other pneumonias. *C. pneumoniae* often causes persistent subclinical infection for many months to years. Many studies have found association between *C. pneumoniae* infection and asthma but the basis for this is not clear.

Diagnosis

Clinical features of pneumonia due to *C. pneumoniae* resemble *Mycoplasma pneumoniae* and influenza infection. Erythrocyte sedimentation rate (ESR) is generally elevated and peripheral WBC count is either normal or increased with neutrophil predominance. Chest X-ray may show findings out of proportion to the clinical status and might include diffuse bilateral involvement or lobar shadows with or without pleural effusion. Isolation of *C. pneumoniae*, antigen detection and detection of DNA by polymerase chain reaction (PCR) from respiratory specimens [throat swab, nasopharyngeal swab, bronchoalveolar lavage (BAL), sputum] and serology are the methods available to detect *C. pneumoniae* infections. The isolation of *C. pneumoniae* in cell culture is technically demanding. Detection of antigen by direct immunofluorescence requires technical expertise and is subjective. Molecular method of detection of *C. pneumoniae* is under evaluation. Detection by culture or antigen test or PCR

does not confirm recent infection as long-term shedding of *C. pneumoniae* is observed in many patients.

Serology is commonly used for routine diagnosis of *C. pneumoniae* infections due to its easy availability and simplicity. Microimmunofluorescence (MIF) test is the commonly used method. Anti *C. pneumoniae* IgM titer of more than or equal to 1:16 or a fourfold rise in IgG titer between acute and convalescent serum specimens confirms acute primary infection. Serological tests have a sensitivity of 60–80% and specificity of 90–100%.

Treatment

C. pneumoniae is susceptible to tetracyclines, macrolides, quinolones and ketolides. Resistance is not common. The following regimen is recommended for treating *Chlamydia pneumoniae* infection in children:

- Azithromycin 10 mg/kg/once a day followed by 5 mg/kg/once daily for 4 days
- Erythromycin 50 mg/kg/day for 10–14 days
- Clarithromycin 15 mg/kg/day for 10 days.

Therapy with antichlamydial antibiotics in patients with asthmatic exacerbations, in whom CP infection is proven or presumed, has shown beneficial effects. This may be due to the antichlamydial effect or immunomodulatory effect of the antibiotics. Antibiotics are highly effective in treatment of acute *C. pneumoniae* infections but their effectiveness for treating chronic infections is limited.

Prevention

Currently there is no vaccine is available for prevention of *C. pneumoniae* infection but evaluation of various antigens for a potential vaccine is underway.

IN A NUTSHELL

1. Children with chlamydial infections usually present with features of lower respiratory infection.
2. It is one of the causes of atypical pneumonia and can present with wheeze.
3. Macrolides are the drugs of choice for therapy.

PART VIII Systemic Disorders

Section 35 GASTROINTESTINAL DISORDERS

Section Editors A Riyaz, John Matthai

Chapter 35.1

Anatomy and Physiology

S Arivu Selvan

The gastrointestinal tract (GIT) constitutes the esophagus, the stomach and the small and large intestines. The esophagus serves as a passage for food from the mouth and pharynx to the stomach. The stomach is the site where the food is thoroughly mixed with gastric secretions. It aids emptying the contents into the duodenum. Absorption of digested food occurs mainly in the small intestine. The liver and pancreas form the major glands of the digestive system. They discharge their secretion into the duodenum. Fecal matter is formed in the descending and sigmoid colons and is collected in the rectum before defecation through the anal canal.

Gastrointestinal tract plays a prominent role in immune function. The low pH of the stomach, and the mucus secreted from it are lethal to microorganisms entering the gut. The enzymes in saliva and bile are other factors helping with immune function. *Helicobacter pylori* are the only bacteria found alive in the stomach. They are considered responsible for gastritis and gastric ulcers.

The microorganisms forming the beneficial flora of the gut prevent overgrowth of harmful bacteria by competing for space and food. A ratio of 4:1 between the beneficial and harmful bacteria is generally considered normal within the intestines. The *gut-associated lymphoid tissue* (GALT) plays a vital role in killing the organisms entering the gut.

DEVELOPMENT OF THE GUT

The development of gut occurs at the beginning of the 4th week of gestation. The trilaminar embryonic disc with the three germ layers is folded upon itself cranially, caudally and side-wise. As a result, the endodermal layer of the disc becomes tubular and forms the inner lining of the gut. During this process, most of the yolk sac communicating with the gut is incorporated into it and contributes to formation of gut. The remaining part of the yolk sac with the vitellointestinal (omphaloenteric) duct (**Fig. 1**) later disappears. Persistence of the vitellointestinal duct gives rise to the *Meckel's diverticulum*.

Following folding of the disc, two pits known as stomatodeum and proctodeum develop at the cranial and caudal ends of the gut respectively. Initially, the two ends of the gut are separated from these pits by the buccopharyngeal and the cloacal membranes, respectively (**Fig. 2**). Later, these membranes rupture and the gut communicates with the exterior at these ends. Failure of rupture of the cloacal (anal) membrane results in *imperforate anus*.

Figure 1 Formation of primitive gut following folding of the embryo

Figure 2 Formation of cranial and caudal pits (stomatodeum and proctodeum)

The foregut gives rise to the upper part of the alimentary canal from the floor of the mouth down to the level of upper part of duodenum marked by the major duodenal papilla. The midgut begins at this level and ends at the junction between the right two-thirds and left one-third of transverse colon. The remaining part of the gut down to the anal canal above the pectinate line is contributed by the hindgut. The lower part of anal canal develops from proctodeum.

The endoderm gives rise to the epithelial lining of the gut; the other layers of the gut are derived from the splanchnopleuric mesoderm surrounding the gut. The glands of the digestive tract and their duct system develop from the foregut as buds or diverticula. During early stage of development, the cells of the neural crest migrate into the wall of the gut and form the enteric nervous system (ENS). *Achalasia cardia* and *congenital megacolon* (Hirschsprung disease) are due to failure of migration of neural crest cells to form the nerve plexuses in the respective parts of the gut.

Rotation of Midgut Loop

In the initial stage, the abdominal cavity is largely occupied by the massive liver and kidneys. There is only little space within the peritoneal cavity to accommodate the rapidly elongating coils of intestines. As a result, during 6th week of development, the midgut loop herniates into the umbilical cord. This is known as *physiological umbilical herniation* and is a normal event in all embryos. Elongation of intestines occurs outside the body.

During 10th week of development, when the abdominal cavity becomes sufficiently larger, the whole of the herniated bowel is withdrawn into the abdominal cavity. During the process of herniation and withdrawal, the midgut loop undergoes 270° rotation in anticlockwise direction. This rotation of the midgut is essential to establish appropriate positions of parts of gut within the peritoneal cavity. Failure of return of the midgut results in *omphalocele* or *exomphalos*. Similarly, incomplete rotation (mixed rotation), rotation in the opposite direction (reversed rotation) or failure of rotation (nonrotation) gives rise to various anomalies associated with abnormal position of parts of the gut in the abdominal cavity (e.g., presence of cecum in the midline below the stomach). Such abnormal positions of the parts of gut are prone to intestinal obstruction due to *volvulus*.

Fixation of the Gut

Initially, the gut is suspended from the posterior abdominal wall by a fold of peritoneum known as the dorsal mesentery. Later, alternate parts of the gut lose their mesentery and become retroperitoneal. Fixation of the gut is essential to retain its appropriate position in the abdominopelvic cavity and to prevent intestinal obstruction due to *volvulus*. The parts of the gut that lose their mesentery include the duodenum except its first part, the ascending colon and descending colon, the rectum and the anal canal. The cecum is covered with peritoneum on all sides. However, it does not have a mesentery.

DEVELOPMENT OF LIVER AND GALLBLADDER

The liver develops as a diverticulum (hepatic bud) extending from the lower part of foregut. This diverticulum soon bifurcates into two parts: pars cystica and pars hepatica. The pars cystica expands to form the gallbladder and the pars hepatica expands to form the parenchyma of the liver (**Fig. 3**). The proximal parts of the diverticulum remain narrow and form the biliary ducts. The stroma of the liver such as sinusoids, Kupffer cells and capsule develop from the *septum transversum*, a fibrous septum that forms part of the diaphragm.

DEVELOPMENT OF PANCREAS

The development of pancreas is marked by two pancreatic buds: ventral and dorsal extending from the lower part of the foregut close to the hepatic diverticulum. Due to rotation of the stomach and differential growth of the duodenum, the buds come closer and fuse to form the pancreas (**Fig. 4**). Insulin secretion begins from 10th week of development. Variations in the formation

Figure 3 Development of hepatobiliary apparatus

Figure 4 Development of pancreas

and mode of termination of the biliary and pancreatic ducts are common. In some cases, the bile duct and the pancreatic duct fail to unite and open independently into the duodenum. *Annular pancreas* is a developmental anomaly in which a ring of pancreatic tissue surrounds the second part of the duodenum. A bifid ventral pancreatic bud is attributed to be a cause of this anomaly.

BLOOD SUPPLY OF THE GUT

The aorta running behind the gut gives off several branches to the gut in the initial stage of development. Later, many of these branches disappear and only three arteries persist. The celiac trunk supplies the foregut from the lower part of esophagus, liver, gallbladder and pancreas, which are the derivatives of the foregut; the superior mesenteric artery (SMA) supplies the midgut and the inferior mesenteric artery (IMA) supplies the hindgut.

Since the duodenum develops from both the foregut and the midgut, it is supplied by the branches of celiac trunk and SMA. The branches of these arteries anastomose to form an arterial arcade around the head of the pancreas. This anastomosis provides an alternative source of blood to the foregut structures in case of occlusion of celiac trunk or its branches.

Since the transverse colon marks the junction between the midgut and the hindgut, it is supplied by both the midgut (SMA) and the hindgut (IMA) arteries. The branches of these arteries anastomose freely and form a circumferential artery known as the *Marginal artery of Drummond* along the inner margin of the colon. This artery supplies the entire colon. In cases of occlusion of the

SMA or IMA, this anastomosis helps to provide blood to the affected part of the colon. However, the area near the splenic flexure where the branches of the two gut arteries meet is least vascular and it becomes a common site of *ischemic necrosis* of colon.

The *jejunum and ileum* are supplied by 15–18 branches arising from the SMA. They unite to form loops or arches called *arterial arcades*, from which straight arteries known as *vasa rectae* arise to supply the jejunum and ileum. These arteries are end arteries to the jejunum and ileum. Therefore, occlusion of *vasa rectae* due to internal hernia or compression by a tumor can produce *gangrene* of the small bowel.

The appendicular artery supplying the appendix ends even before reaching its tip in most of the cases. Therefore, the tip becomes least vascular and suffers gangrenous changes first in *acute appendicitis*.

The veins draining the gut form the *portal venous system*. The superior and inferior mesenteric veins collect blood from the midgut and the hindgut respectively. The veins from the foregut, pancreas, spleen and most of the gallbladder empty their blood into the portal vein either directly or indirectly through the splenic vein. The portal vein carries blood to the liver through its hilum. This blood after undergoing metabolic changes and detoxification in the liver is emptied into the inferior vena cava through hepatic veins that emerge from the liver.

Unlike the systemic veins, the veins of the portal system are devoid of valves. Therefore, blood flow can occur in either direction depending on pressure changes. The veins of the portal system anastomose with systemic veins (portosystemic anastomosis) in five regions of the abdomen. In portal obstruction or hypertension due to cirrhosis of liver, the blood flow through the liver slows down and blood backs up throughout the portal system. The tributaries of the portal venous system are very much engorged at the sites of portosystemic anastomoses.

INNERVATION OF THE GUT

The GI tract is innervated by both intrinsic innervation through ENS, and extrinsic innervation through autonomic nervous system. ENS referred to as the *minibrain of the gut* organizes and coordinates the activity of musculature, glands, and blood vessels of the gut. Functionally, it consists of three types of neurons: motor, sensory and interneurons. Musculomotor neurons (excitatory and inhibitory) control the contraction and relaxation of musculature of the gut. Secretomotor neurons control the secretory activities of the glands; the sensory neurons receive information regarding the state of the gut, and the interneurons form information-processing networks through their synaptic interconnections. The neurons of the ganglia and their fibers form the two nerve plexuses of the ENS. *Myenteric (Auerbach's) plexus* is primarily concerned with initiation and control of smooth muscle contraction and relaxation such as peristalsis. *Submucosal (Meissner) plexus* coordinates reflexes associated with secretion and absorption, as well as motor control of smooth muscle. Both these plexuses communicate freely within the wall of the gut.

The *parasympathetic fibers* innervating the foregut and midgut originate from the dorsal vagal complex (cranial outflow) in the medulla. The parasympathetic fibers innervating the hindgut originate from the S₂, S₃, S₄ spinal segments (sacral outflow). They form the pelvic splanchnic nerves (*nervi erigentes*). The parasympathetic innervation exerts both excitatory and inhibitory effects on the gut. The efferent vagal fibers synapsing with neurons in the ENS activate circuits to the effector systems. In the case of musculature, they exert reciprocal control over both inhibitory and excitatory musculomotor neurons. These neurons send signals to the musculature of gut both in anticipation of food intake and

following a meal. In the case of glands, the secretomotor neurons are activated to stimulate secretion of the glands. The afferent vagal fibers (visceral afferents) send signals from the gut to the ENS in response to distension of the gut from food. These vagal afferent neurons are connected with a variety of sensory receptors (physical, chemical, and thermal) in the gut. They detect physical parameters such as brushing of mucosa with food, changes in muscle tension, and changes in chemical parameters such as pH, glucose concentration and osmolarity.

The *sympathetic fibers* innervating the gut innervate mainly the blood vessels to produce vasoconstriction, and also mucosa, and musculature of the gut. They suppress gut activity when stimulated. Sympathetic suppression of digestive functions, including motility and secretion, occurs secondary to reduced blood flow mediated by the *norepinephrine* released from sympathetic postganglionic neurons. It acts directly on sphincteric muscles (*lower esophageal sphincter* and *internal anal sphincter*) to keep them closed by increasing their tension.

MICROSCOPIC STRUCTURE OF THE GUT

The wall of the GIT consists of four major layers: mucosa, submucosa, muscularis propria, and serosa (if covered with peritoneum) or adventitia (if not covered with peritoneum). The mucosa, in turn, consists of a lining epithelium, lamina propria of loose connective tissue and muscularis mucosae, a thin layer of smooth muscle. The mucosa differs considerably from region to region based on functional changes in different parts of the gut.

Stomach

The tall columnar epithelium lining the stomach invaginates to form the gastric pits, into which the gastric glands secrete. The gastric glands are composed of four types of epithelial cells:

1. *Mucous neck cells* secrete mucus, which forms a thick lining of about 1 mm thickness on the luminal surface.
2. *Chief cells* produce pepsinogen, a precursor of the proteolytic enzyme pepsin.
3. *Parietal cells (or oxyntic cells)* secrete the gastric acid. In addition to activating the pepsinogen, the gastric acid effectively sterilizes the contents of the stomach. They also secrete *intrinsic factor*, which is necessary for the absorption of vitamin B₁₂.
4. *Argentaffin cells (unicellular endocrine glands)* are found scattered throughout the epithelium of the GIT. They include gastrin-producing cells (*G cells*) and somatostatin-producing cells (*D cells*). *G cells* stimulate the secretion of acid and pepsinogen. *D cells* are activated by acid in the lumen of the stomach and duodenum. They inhibit *G cells* and thereby acid production.

Other types of endocrine cells include vasoactive intestinal polypeptide (VIP)-producing cells (or *D1 cells*) and serotonin-containing cells (enterochromaffin cells). Endocrine cells in the GIT are alternatively named *amine precursor uptake and decarboxylation (APUD) cells*.

Small Intestine

The intestinal mucosa contains numerous *villi*. Each *enterocyte* or the lining epithelial cell forms several *microvilli (brush border)*. The simple tubular glands of intestine (*crypts of Lieberkühn*) open between the villi. Four types of cells are found throughout the mucosa of the intestinal villi. Some have absorptive function while others secrete digestive enzymes and mucus to protect the intestinal lining from digestive actions. The following are the cell types: (1) *simple columnar absorptive cells*; (2) *goblet cells producing protective mucus*; (3) *Paneth cells*, producing lysozyme

capable of digesting bacterial cell walls; and (4) *argentaffin* or enteroendocrine cells, which produce gut hormones like *cholecystokinin* and *secretin*. Cholecystokinin stimulates the secretion of digestive enzymes in the pancreas and the contraction of the gallbladder. Secretin stimulates the pancreas to release *pancreatic juice*. It also augments the effects of cholecystokinin.

The crypts of Lieberkühn secrete the *intestinal juice* (*succus entericus*). A few enzymes are found in the intestinal juice. These include the *amylase* and the *enteropeptidase* (enterokinase). The latter activates the pancreatic enzyme trypsin which in turn activates all proenzymes secreted by pancreas to their active forms. The lymphocytes in the lamina propria form solitary lymphoid nodules known as *Peyer's patches* in the ileum.

The duodenum is characterized by the presence of the *glands of Brunner* in the submucosa; their secretion protects the duodenal mucosa just like the mucus in the stomach.

The lacteals are the specialized lymphatic vessels found in the intestinal villi. They absorb the end-products of fat digestion. They empty their milk-like fluid into the lymphatic plexuses in the walls of the jejunum and ileum.

Large Intestine

Since the mucosa of large intestine is devoid of villi, the mucosal surface is flat with several deep intestinal glands. It contains numerous goblet cells that secrete mucus to lubricate fecal matter as it solidifies. It harbors several kinds of bacteria that help breaking down of molecules, which the gut is not able to break down itself. This is an example of symbiosis. Colon is sterile at birth; colonization of bacteria occurs within a few hours. This is essential for digestion and formation of vitamin K. Further, the intestinal flora helps in the synthesis of vitamin B complex. These bacteria also account for the production of gases.

Liver

The parenchyma of liver is composed of several *hepatic lobules*. Each hepatic lobule is a hexagonal structural unit with hepatocytes arranged in the form of sheets or cords radiating outward from a central vein like the spokes of a wheel. Located between the hepatic cords are the sinusoids, which receive blood at the periphery of the lobule from the portal vein and the hepatic artery and, after traversing the lobule, discharge the blood into the central vein at the center of the lobule. The sinusoids are lined with endothelial cells and contain the stellate cells of Von Kupffer. Bile capillaries (canaliculi) are formed between adjacent hepatic cells, which drain toward the periphery of the hepatic lobule into a bile ductule in the portal canal. This structural unit of the liver is repeated throughout the liver.

Another way of considering the function is a triangular or biliary unit known as *portal lobule*, the corners of which are formed of three central veins. This approach emphasizes the secretion of bile and the biliary system; bile from the canaliculi drain into bile ductules at the center of the triangular unit (portal lobule) (Fig. 5).

The third unit of structure/function is the *hepatic acinus*. Each acinus is a diamond-shaped unit connecting the two adjacent hepatic lobules. The central veins are located at the diametrically opposite angles and portal triads are located at the other two diametrically opposite angles of the diamond. Each hepatic acinus is divided into three *zones*. There is an oxygen gradient (from high to low) between zones 1, 2 and 3. The cells of the zone 3, being least oxygenated are the first to undergo necrosis due to ischemia or drug reaction. After a meal, glycogen will be stored first in the zone 1, later in zone 2, and finally in zone 3. The reverse is true when glucose is needed: zone 3 is depleted of its glycogen first, followed by zones 2 and 1.

Figure 5 Anatomic and functional lobules of liver

Pancreas

Pancreas is subdivided into several lobules separated by connective tissue septae. Each lobule consists of several compound tubuloalveolar glands with purely serous alveoli. The glandular epithelium consists of pyramidal cells, which secrete zymogen granules into a system of ducts. The centroalveolar or centroacinar cells lie between the secretory cells and the lumen of the alveolus. Interspersed between the exocrine parts of the pancreas are the cells of islets of Langerhans. They are found in abundance near the tail end of the pancreas. Four types of cells constitute the islets: *alpha cells* secreting glucagon, *beta cells* secreting insulin, *delta cells* secreting somatostatin and *PP cells* secreting pancreatic peptide.

IN A NUTSHELL

1. In addition to digestion and absorption of food, the GIT plays significant role in immune function.
2. The liver, the gallbladder and the pancreas including the respiratory tract and the lungs develop as diverticula from the wall of the foregut.
3. Elongation of the intestines occurs outside the body of the embryo and the midgut loop undergoes 270° rotation in the anticlockwise direction during this process. Failure of return of the midgut to the abdominal cavity after elongation results in omphalocele or exomphalos.
4. During initial stage of development, the entire gut is suspended from the posterior abdominal wall by the dorsal mesentery and is therefore intraperitoneal in position. Later, alternate parts of the gut lose their mesentery and become retroperitoneal. The fixation of the gut in this manner is essential to retain their appropriate position in abdominal cavity and to prevent intestinal obstruction such as volvulus.
5. Besides the nerve plexuses of the ENS, the sympathetic innervation to the gut is provided by T5-T6 to L2-L3 spinal segments and the parasympathetic innervation is provided by the vagus and the pelvic splanchnic nerves (S2, S3, S4).
6. Pain impulses from the gut down to the middle of the sigmoid colon are conveyed through the sympathetic fibers and, caudal to this level by the parasympathetic fibers.
7. From within outward, the mucosa, submucosa, muscularis externa and serosa or adventitia are the four major layers forming the wall of the gut.

Chapter 35.2

Common Symptoms of Gastrointestinal Diseases

Sarah Paul, John Matthai

Symptoms related to gastrointestinal (GI) system are common in children. In most cases, they are indicative of a mild disease, while in some, they are pointers to serious underlying disorders. Not infrequently, they are functional, psychogenic or stress-related. While systemic diseases may manifest with abdominal symptoms, GI diseases need not always have symptoms referable to the GI tract. A basic understanding of the pathophysiology of the common signs and symptoms will help avoid unnecessary investigations and parental anxiety.

DIARRHEA AND DYSENTERY

Increase in frequency, fluidity and volume of feces in relation to the age of the child is called diarrhea. In epidemiological studies, diarrhea is defined as the passage of three or more loose or watery stools during a 24-hour period, a loose stool being one that would take the shape of a container. The most common type is the acute watery diarrhea where the illness starts acutely, lasts less than 14 days (most episodes last less than 7 days), and involves the passage of frequent loose or watery stools without visible blood. Diarrhea with visible blood in the feces is called dysentery and signifies inflammation of the intestinal mucosa. Children appear sick and systemic signs like fever, anorexia and abdominal pain last much longer.

Watery stools are common in either osmotic or secretory diarrhea. Small bowel mucosa is a porous epithelium through which water and salts move across rapidly to maintain osmotic balance between the bowel contents and the blood. Diarrhea occurs when a poorly absorbed, osmotically active substance (usually a carbohydrate) is present in the gut lumen. The stooling stops on fasting, the stool pH is acidic and reducing substances are positive. Removal of the unabsorbed component of the diet is the only treatment. The unabsorbed substance is usually isosmotic and therefore dehydration and electrolyte disturbances are unlikely. Secretory diarrhea is caused by toxins [for example, cyclic AMP of cholera, cyclic GMP of enterotoxigenic *Escherichia coli* (ETEC)], which impair sodium absorption by the villus cells, while the chloride secretion by the crypt cells continues. The stooling continues despite fasting, the stool pH is alkaline and reducing substances are negative. Dehydration and electrolyte imbalances are common. Ion transport disorders (congenital chloride or sodium diarrhea) present with watery stools in the newborn period and result in failure to thrive and severe electrolyte disturbances. Increased gut motility from VIPoma, carcinoid or thyrotoxicosis are rare in children, but should be considered in chronic watery diarrhea when other causes are ruled out. Dysentery occurs from an inflammatory diarrhea and may be either infective (*Shigella*, *Salmonella*, amebiasis) or noninfective [inflammatory bowel disease (IBD), cow's milk protein allergy].

ABDOMINAL PAIN

Differentiating the varied types of functional abdominal pain from those with an organic pathology is a big challenge in practice. Pain-related functional GI disorders were categorized into five groups in the Rome III criteria of 2006: functional dyspepsia, irritable bowel syndrome, abdominal migraine, childhood functional abdominal

pain, and childhood functional abdominal pain syndromes. It is important however to recognize signs and symptoms that are suggestive of an underlying organic disease (**Table 1**).

Clinically, there are three patterns of abdominal pain in children: (1) Isolated per-umbilical pain, in which only 5% are organic causes (malrotation, renal stone, pelviureteric junction obstruction, food allergy); (2) upper abdominal pain with dyspepsia, in which 10% are organic [gastroesophageal reflux disease (GERD), *H. pylori*, pancreatitis, biliary disease and food intolerance] and (3) lower abdominal pain with altered bowel habits in which over 25% have an organic basis (constipation, IBD, lactose intolerance and gynecological). A careful history is important and helps avoid unnecessary investigations.

VOMITING

Vomiting, a complex protective reflex which helps rapid expulsion of any ingested toxins has three linked components: nausea, retching and emesis. It is a common symptom that occurs in many disease states, the cause of which is age-related. While congenital anomalies of the GI tract, necrotizing enterocolitis and inborn errors of metabolism are the most common causes in neonates, infections of the GI and hepatobiliary system, urinary tract and CNS as well as food allergy/intolerance predominate in infants and young children. In infants, it is important to distinguish reflux, which is the effortless passive bringing up of gastric contents, and involves no muscular activity. Gastroesophageal reflux is a physiological phenomenon that improves with age and most infants remain healthy. At any age, presence of any of the following features is very suggestive of an abdominal surgical cause: persistent vomiting with distended abdomen or constipation, bilious vomiting, absent bowel sounds, GI bleeding, point tenderness or diffuse guarding. Altered sensorium points to a CNS cause, electrolyte imbalance, liver/renal failure, diabetic ketoacidosis or poisoning.

In patients with recurrent episodes of vomiting, malrotation of gut, superior mesenteric artery syndrome, obstructive uropathy, chronic pancreatitis, diabetes, adrenal insufficiency, CNS lesions as well as inborn errors of metabolism should be considered. Cyclic vomiting syndrome is essentially a diagnosis of exclusion and is characterized by episodes of persistent vomiting without an identifiable cause, interspersed with complete symptom-free periods. The episodes may last up to 72 hours, cease spontaneously and often result in dehydration and electrolyte disturbances. Some have a family history of migraine and respond to antimigraine prophylaxis. The routine use of antiemetics in infants and children without a clear understanding of the underlying disease should be discouraged.

CONSTIPATION

Constipation is defined as delay or difficulty in defecation that causes significant distress to the child. If it persists more than two weeks, it is referred to as chronic constipation. Acute constipation is easier to treat and usually caused by a change in feeds, addition of formula in infants, sudden change in diet or place of stay, low-fiber diet, anal fissure or drugs. Chronic constipation is generally diet- and habit-related and presents a challenge in management.

Table 1 Features suggestive of an organic cause in chronic abdominal pain

• Localized or radiating pain	• Dysphagia
• Pain that wakes the child from sleep	• Persistent vomiting
• Gastrointestinal bleeding	• Malabsorption stool
• Growth deceleration or weight loss	• Unexplained fever
• Chronic GI disease in family	• Oral ulcer/perianal disease

Organic causes of chronic constipation are given in **Table 2**. While examination of the spine and the anal region is mandatory in all children with constipation, rectal examination should be avoided unless indicated. Associated urinary tract infection should be ruled out.

Encopresis is the involuntary passage of semiformed stool in a child's inner wear and is generally seen with functional constipation. Fecal incontinence is consistent fecal soiling and usually seen in association with an organic or anatomic lesion.

MALABSORPTION

Malabsorption is said to be present when there is a persistent disturbance of the digestive-absorptive process across the intestinal mucosa and is usually associated with growth faltering. The normal process of digestion involves three important steps: solubilization (fats by micelle formation), digestion (by specific digestive enzymes) and mucosal absorption (by diffusion or carrier-mediated transport). Maldigestion occurs when the amount of bile or pancreatic enzymes in the intestine is inadequate; for example, cholestasis and pancreatic insufficiency. Classical malabsorption occurs when there is a mucosal disease and defective absorption; for example, celiac disease, giardiasis and cow's milk protein allergy. The stools are pale, bulky with steatorrhea and foul smell in impaired fat digestion and explosive watery in defective carbohydrate digestion. In malabsorption, the child has flatulence and bloating; the stool contains both fat globules and fatty acid crystals, and there is associated anemia and hypoalbuminemia. In maldigestion, there is no bloating; the stool contains only fat globules and the child has no anemia or hypoalbuminemia.

GASTROINTESTINAL HEMORRHAGE

Upper GI bleeding defined as bleeding above the ligament of Treitz (esophagus, stomach and duodenum) presents with hematemesis. Only sudden massive bleeding causes bright red blood, since exposure to gastric juice quickly changes the color to coffee ground. While swallowed maternal blood and hemorrhagic disease are the most common cause in a well neonate, stress ulcer, coagulopathy and vascular anomaly should also be considered. In older children, esophagitis, gastric erosions and varices are relatively common, while prolapse gastropathy, Mallory-Weiss tear and vascular lesions are unusual causes. An upper GI endoscopy is the investigation of choice. A significant upper GI bleed can result in melena for three to five days.

Lower GI bleeding refers to bleeding beyond the ligament of Treitz and presents in two different ways:

1. Melena refers to black tarry stools, the black color being due to hematin, formed by the oxidation of haem by intestinal bacteria. Melena usually occurs when the bleeding is proximal to the ileocecal valve, but can occur in proximal colonic bleeds if the colonic transit time is slow.
2. Hematochezia is the presence of red blood in stool and is seen in colonic disease or in massive bleeds in the small intestine. Necrotizing enterocolitis, Hirschsprung enterocolitis and malrotation with volvulus are common causes in a neonate. While infectious enterocolitis, anal fissure and milk protein allergy are causes of mild bleeding in infants and young

children, Meckel's diverticulum and intussusception can cause massive blood loss. In older children, infectious colitis, polyp, hemorrhoids, IBD and Henoch-Schönlein purpura require consideration. Hematochezia limited to spots or streaks on the outside of the stool suggest an anorectal source. However, if it is mixed through the stool, it suggests a local pathology above the rectum and if it is seen with mucous in a loose stool, it is characteristic of colitis. Maroon-colored blood suggests significant bleeding in the distal small bowel and currant jelly stools are indicative of ischemic bowel lesion as in intussusception or volvulus. In melena, the more proximal the bleed, the darker black will be the stool.

ABDOMINAL DISTENSION

Abdominal distension is either due to a lax abdominal wall, a mass in the abdomen or from accumulation of fluid or gas within or outside the intestine. Ascites in significant amount distends the abdomen both anteriorly and in the flanks. The ascitic fluid is usually a transudate with low protein concentration and commonly results from increased portal venous pressure and/or reduced oncotic pressure from hypoalbuminemia. Portal hypertension per se is unlikely to cause clinically apparent ascites, until serum albumin declines. Exudative ascitic fluid has a high protein concentration and indicates an inflammatory pathology. When fluid or gas distends the gut, a mechanical or functional obstruction of the gut should be suspected. While gas filled loops of intestine will yield a tympanitic resonance over the periumbilical area, gas in the peritoneal cavity will result in a tympanitic resonance even over the solid organs like the liver. Localized abdominal distension can occur from enlargement of liver, spleen and kidney, a tumor or a congenital or acquired cyst.

IN A NUTSHELL

1. Watery stools indicate small bowel pathology, commonly of viral etiology.
2. Dysentery is diarrhea with visible blood in the stool and implies a large bowel disease.
3. Periumbilical episodic abdominal pain is functional in most children.
4. In children with persistent vomiting, intestinal surgical causes and extraintestinal medical causes should be considered.
5. Chronic constipation in young infants has an organic basis, while in older children, it is functional.
6. Hematemesis indicates bleeding above the ligament of Treitz and requires upper GI endoscopy.
7. Hematochezia occurs in distal colonic disease while melena suggests bleeding proximal to the ileocecal valve.

Meningomyelocele	Hypokalemia, hypercalcemia

Chapter 35.3

Cleft Lip and Cleft Palate

VS Akbar Sherif, Sayed Mohammed Akbar

Cleft lip (CL) and cleft palate (CP) are the most frequently encountered congenital anomalies of the craniofacial region. In India, about 30,000 babies with a cleft are born every year. The main categories of cleft are CL, CP, or CL and CP. They can present as an isolated anomaly, as part of a syndrome or associated with other anomalies.

Children affected with cleft will have a range of esthetic and functional problems, which leads to poor feeding, repeated ear and chest infections, malnutrition and even death in some cases. This situation has improved in recent times after the NGO—Smile Train began participating in surgical repair programs all over India. In 2008, WHO included CL and CP in the noncommunicable disease category in the Global Burden of Disease Initiative.

EPIDEMIOLOGY

The global prevalence of orofacial cleft is 1 in 700 livebirths. Males are more affected than females. Isolated CP is seen more in females. For reasons not known, left side is more affected than right. 75% clefts are unilateral and 25% bilateral. The risk for the next sibling getting affected is as follows:

- *Normal parents with one cleft child* 4% risk for the next child to have CL/CP
- *Normal parents with two kids with CL/CP* 9% risk for the next sibling
- *One parent affected with CL/CP, no affected kid* 4% risk for the next child
- *One parent and one child with CL/CP* 17% risk for the next child.

Siblings of babies with severe forms of CL/CP carry a high-risk of acquiring clefts. By high resolution ultrasonography, orbicularis oris muscle discontinuity has been demonstrated in relatives of patients with nonsyndromic clefts.

ETIOLOGY

The exact etiology is not known but is believed to be multifactorial involving both genetic and environmental factors. Although facial clefts occur in a variety of genetic syndromes, identification of a single gene controlling lip and palate cleft has not yet been identified. About 15% of the clefts are syndromic and more than 170 syndromes have cleft as a feature. Certain specific chromosomal aberrations are consistently seen, like trisomy D syndrome with midline cleft, 22q11.2 in velocardiofacial syndrome (CATCH 22). Few environmental factors are known to increase the incidence of clefting. They include factors like drugs (phenytoin, retinoic acid), maternal smoking, alcohol, folate deficiency and rubella infection in early pregnancy.

EMBRYOPATHOGENESIS

Craniofacial region develops through active migration of cells and the rearrangement of facial prominences and pharyngeal arches. Hence, this area is more vulnerable to many congenital birth defects. The special cells which contribute for the majority of skeletal and connective tissue of the craniofacial region are the pluripotent neural crest cells. Upper lip develops by the 4th week of embryonic life as five prominences arranged around the future mouth, the stomodaeum. They are the single frontonasal process (FNP), paired maxillary and mandibular processes. The maxillary

and mandibular processes originate from the 1st branchial arch. Fusion of maxillary and FNP completes the formation of upper lip (**Fig. 1**). The lower lip and the lower jaw are formed by the fusion of the two mandibular processes in the midline. Fusion of maxillary and mandibular processes will complete the formation of cheek and angle of mouth (**Fig. 2**).

The palate develops later around 7–8 weeks of intrauterine life. The two palatal process of maxilla meet with each other in the midline and also with the premaxilla anteriorly. Initially, the palatal processes are vertically oriented because of the presence of developing tongue in between it. As the oral cavity develops space, the tongue will fall back allowing the palatal process to move horizontally and fuse in the midline. Pathological states where the tongue is too big or the capacity of the oral cavity is small will result in a CP. Classical example is the Pierre-Robin syndrome (**Fig. 3**).

Failure of fusion between maxillary and medial nasal process results in classical cleft lip (**Fig. 4**). If the fusion defect is bilateral, it results in bilateral cleft lip (**Fig. 5**). The lip and palate develop separately which means it is possible for a baby to be born with only CL, only CP or a combination of both.

CLASSIFICATION

Numerous methods have been developed for recording cleft deformities but none of them are accepted universally due to limitations, inadequate description of deformity and varying complexities. There are four basic structures involved in CL/CP. They are nose, lip, primary and secondary palate. These basic structures may be involved completely or incompletely in many combinations. The morphological classification given below helps the clinician to understand the severity, grading, communication and treatment planning.

- *Isolated CL/CP* Unilateral/bilateral: Complete/incomplete
- *Combined CL/CP* Unilateral/bilateral: Complete/incomplete
- Syndromic.

CLINICAL PROBLEMS

Besides the obvious facial deformity from an external cleft, immediate functional concerns are for airway patency and the

Figure 1 Formation of upper lip

Figure 2 Formation of cheek and angle of mouth

Figure 3 Pierre-Robin syndrome. Note small and receding chin

Figure 4 Unilateral cleft lip

Figure 5 Bilateral cleft lip

ability to feed. Certain clefts like the Pierre-Robin sequence will have severe life-threatening respiratory distress which may require immediate attention.

Feeding Problems

Normal feeding requires the creation of suction by velopharyngeal closure and compression by the orbicularis oris muscle and tongue. Babies with CL/CP cannot create a negative pressure for suction or compression. So, they may be given expressed breastmilk using special feeding devices or breastfed using feeding obturators. The baby should be fed every 2 hours, in a calm and quiet environment with the caregiver sitting in a comfortable chair. The teat should be kept on the uncleft side and gently squeezed after every 3–4 sucks. Feeding should not exceed to 20–30 minutes, since longer feeds are energy-consuming leading to poor weight gain. If bottle fed, the baby should be kept upright to prevent nasal regurgitation. Special teat or bottle which can be squeezed while the baby is sucking is now available. This will push the milk into baby's mouth and will compensate for suction.

Nasal Regurgitation and Aspiration

In babies with CL/CP sucking and swallowing mechanisms are defective, which leads to repeated aspiration pneumonia. Aggressive treatment may be needed to control the pneumonia. Feeding the baby with head-up position will decrease the problem until they learn adaptive techniques to overcome the handicap.

Middle Ear Infection

A majority of CP/CP patients develop middle ear infections, which if recurrent leads to conductive hearing loss. This predisposition may persist even after CP repair. The tensor palatini muscle is attached to the cartilaginous part of eustachian tube. Normally when this muscle contracts as in the act of swallowing or yawning, it will open up the eustachian tube equalizing the pressure in the middle ear and allowing drainage of any secretion. In babies with cleft palate, the action of this muscle is ineffective leading to fluid accumulation and infection. Also the eustachian tube is directly exposed in these babies, with regurgitation of milk feeds leading to edema and infection. Adenoid hypertrophy secondary to repeated infections also contributes to eustachian tube obstruction.

Speech Problems

The suction and compression of the breast during the normal feeding produces a coordination of these muscles, which is essential for normal speech development. This co-ordination is missing in children with cleft palate. The other factors which contribute to the poor speech development are velopharyngeal incompetence, palatal fistula, poor hearing, dental malocclusion and psychological factors. Hypernasality of speech is very common.

Psychosocial Problems

The facial appearance of babies with cleft interferes with early mother-child bonding. Patients with CL/CP show very low self-esteem and have difficulty in social interactions. Family environment is very important in rehabilitation of these children.

Dental Problems

Children with cleft may have special problems related to missing, malformed, malpositioned teeth. The first orthodontic evaluation is done before dental eruption and helps assess the facial growth, especially the growth of the jaws.

DIAGNOSIS

Craniofacial clefts can be diagnosed by antenatal ultrasonography, as early as 18–20 weeks of gestation. Antenatal diagnosis gives the family time for prenatal education, prenatal psychological preparation and counseling. After birth, minor forms of clefts like the forme fruste cleft lip or the submucosal cleft palate may

produce diagnostic confusion. Submucosal CP presents with nasal regurgitation, otitis media and poor speech. Examination will show a bifid uvula, midline of palate showing a pearly white line due to mucosal union alone. This will require treatment like any other CP.

MANAGEMENT

Considering the anatomical complexity of cleft, its effect on multiple orofacial functions, and its effect on orofacial growth and development, a multidisciplinary team approach is mandatory for optimal results. Prenatal diagnosis and parental interaction with the cleft team will lay the foundation for the subsequent surgical correction. After birth, attention should be given to ensuring the patency of airway, proper feeding advice and ruling out associated anomalies.

The goals of surgical treatment include repair of birth defect without affecting the growth of face, achieving normal speech, language and hearing, ensuring functional dental occlusion and dental health, optimizing psychological and developmental outcome, and facilitating ethically sound, family-centered sensitive care in a cost-effective manner. The currently recommended treatment schedule is as follows:

- *Birth* Initial assessment, presurgical evaluation and orthodontics
- *3–6 months* Primary lip repair
- *9–12 months* Palate repair (before speech develops)
- *2 years* Speech assessment
- *3–5 years* Lip revisions
- *8–9 years* Initial intervention orthodontics
- *10 years* Alveolar bone grafting
- *16 years* Nasal revision
- *17–20 years* Orthognathic surgery.

Surgical Repair

The many types of surgical repairs available emphasize the fact that each cleft is different. Every patient should be explained the number of surgeries they need including secondary corrections and alveolar bone grafting. CL is traditionally repaired before palate repair between 3 months and 6 months. The rule of 10 (10 g hemoglobin, 10 pounds weight and 10 weeks of age) is useful as an initial criteria for patient selection for surgery. Preoperative orthodontic care involves repositioning of the displaced dentoalveolar segments with various intraoral and extraoral orthodontic appliances, and this makes the surgical correction easier. The nasoalveolar molding device (NAM) is most commonly used.

The ideal technique for palatoplasty is the one which gives perfect speech without affecting maxillofacial growth and hearing. *The surgical steps are:* Closure of the defect, correction of abnormal position of muscle tensor palatini, reconstruction of muscle sling, push back of soft palate to improve velopharyngeal valve

mechanism during speech, minimum raw area to be left either in the oral or nasal surface and tension-free suturing. Grafting of the tooth bearing portion of the maxilla completes the primary repair sequence of the original cleft deformities. This procedure is usually done around 10 years of age.

Despite optimal primary repair, most patients require secondary revision of lip, nose or both. Common secondary corrections include scar revision, vermilion realignment, philtral lengthening, nasal base rotation or nasal tip cartilage correction. Most of this scar revisions are done between 2 years and 4 years to allow scar maturation to occur before the child enters the school. Septorhinoplasty reconstructions are done once they pass the growth phase. Hypernasality of speech with velopharyngeal incompetence is a common sequel of palate repair. Corrective pharyngoplasty is done after confirmation by nasal endoscopy and video fluoroscopy. Some patients may also require orthognathic surgery at around 20 years to correct the midfacial hypoplasia of maxilla, malocclusion and cross bite.

IN A NUTSHELL

1. The global prevalence of orofacial cleft is 1 in 700 livebirths. Males are more affected. Left side is more affected; only 25% clefts are bilateral.
2. The exact etiology is not known but is believed to be multifactorial involving both genetic and environmental factors.
3. There are four basic structures involved in cleft lip and cleft palate. They are nose, lip, primary and secondary palate.
4. Besides the obvious facial deformity from an external cleft, immediate functional concerns are for airway patency and the ability to feed.
5. The goals of surgical treatment include repair of birth defect without affecting the growth of face, achieving normal speech, language and hearing, ensuring functional dental occlusion and dental health, optimizing psychological and developmental outcome, and facilitating ethically sound, family-centered sensitive care in a cost-effective manner.

Chapter 35.4

Dental Caries

Madhu S

Dental caries is considered to be the single most common chronic childhood disease. It is found to be more common than asthma in children. The disease is neither self-limiting nor amenable to treatment with antibiotics. Proper advice given at the right time often helps the child to remain caries free or at least limit the severity of the lesion. The pediatrician, often the first medical professional to see the child is in a unique position to influence the child and the parent. It is extremely important for the pediatrician to know the details regarding the causes and preventive strategies available for this very common childhood disease. The disease often regarded and neglected as dental disease has the potential to cause severe bacteremia leading to worsening of the existing systemic conditions.

EPIDEMIOLOGY

Dental caries is a disease that occurs in proportion to the state of civilization. The main factors implicated in increased dental caries are the production of sugar commercially and increased use of refined food. The incidence of caries is directly proportional to sugar intake. Studies in 20th century showed a high incidence of caries in USA and European countries, whereas it was low in developing countries in Africa. In developed countries, the incidence of caries is in the reversal phase at present due to the preventive strategies taken. However, it is actually increasing in the developing countries due to the increased use of refined food and poor oral hygiene. The incidence of caries is low in children whose parents have low incidence of caries. This could be due to lesser vertical transmission of cariogenic microorganisms or due to the resistant structure of enamel, and quantity and quality of salivary factors acquired from the parents. The role of dietary factors is well-known. A definite correlation is now established between soft drink usage and dental caries.

ETIOPATHOGENESIS

Currently, the term dental caries is used to describe the signs and symptoms of a localized chemical dissolution of the tooth surface caused by metabolic events taking place in the biofilm (dental plaque) covering the affected area. This occurs in an interplay between the tooth, saliva, diet, microorganism and time. The basic hydroxyapatite crystal is constantly modified during and after development of enamel. Two ions constantly involved in the replacement of lattice crystals are carbonate and fluoride. With carbonate ion inclusion, the crystal becomes weak and with fluoride ion, it becomes strong. Trace elements also decide the demineralization-remineralization potential (**Table 1**). Higher the salivary clearance rate, better the caries protective effect. Increased dental caries is seen in conditions involving hyposalivation or xerostomia (**Table 2**). Salivary enzymes, immunoglobulins and buffers contribute to its antibacterial property (**Table 3**).

Role of Sucrose

Probably among all the etiological factors, diet is the main factor which can be controlled by the child and parent. Sucrose is considered to be the arch rival of tooth. In the presence of cariogenic microorganism, mutans are produced from sucrose, which help to form adherent plaque on tooth which help *Streptococcus mutans* to form the initial colony on tooth surface. The habit of snacking in between meals by children has a direct link to dental caries.

Table 1 Trace elements in enamel and its effect on dental caries

Trace elements	Effect
Flourine, phosphorus	Cariostatic
Molybdenum, vanadium, copper, strontium, lithium, gold	Mildly cariostatic
Selenium, magnesium, cadmium, platinum, lead, silicon	Caries potentiating

Table 2 Medical conditions with xerostomia and medications increasing susceptibility to dental caries

Disease	Use of medicine
Sjögrens syndrome	Antihistaminics
Salivary gland malignancies	Narcotics
Diabetes mellitus	Antidepressants
Thyroid disorders	Antihypertensives

Table 3 Salivary antibacterial property

Enzymes	Immunoglobulins	Buffers
Lysozyme	SlgA	Bicarbonates
Lactoferrin	IgG	Salivary proteins
Lactoperoxidase	IgM	Phosphates

This is because more time is available for the bacteria to act. Sticky chocolates and bakery items eaten frequently by the child also lead to increased food retention and caries. The main organisms associated with dental caries are *Streptococcus mutans* group, Lactobacilli species, filamentous bacteria, *Veillonella* species and *Streptococcus* other than mutans group (**Fig. 1**).

TYPES OF DENTAL CARIES

Pit and fissure caries seen on the deep pits and fissures of occlusal surface of molars and premolars (**Fig. 2A**), and smooth surface caries seen on the proximal surfaces (**Fig. 2B**) are the two main types of caries. In children, nursing caries warrants special attention. It is a unique pattern of tooth destruction seen exclusively in primary dentition. Different studies show prevalence as high as 45% in India. It is due to prolonged improper night feeding. Children fall asleep while bottle feeding, and there is prolonged pooling of milk in the oral cavity. The lower anterior teeth are somewhat protected due to the physical presence and cleansing action of tongue (**Fig. 3**). Proper instruction to the parents can completely prevent or limit this condition (**Box 1**). Rampant caries, another type of early childhood caries, can affect both primary as well as permanent dentition. The usual contributory factors are a reduced salivary flow due to any disease state of salivary glands, children treated with tranquilizers, Sjögren syndrome, and genetic factors. Night feeding with milk or sugar-containing juices, nutritional deficiency, improper diet and emotional disturbances can all be contributory to this condition (**Fig. 4**).

BOX 1 Instructions to parents to prevent nursing caries

- Avoid feeding while sleeping after 1 year
- Oral cavity should be wiped clean with a cloth after each feed
- If child has the habit of sleeping with milk, discourage it
- Reduce the amount of sugar in the milk or juices gradually
- Encourage the child to drink warm water after each feed.

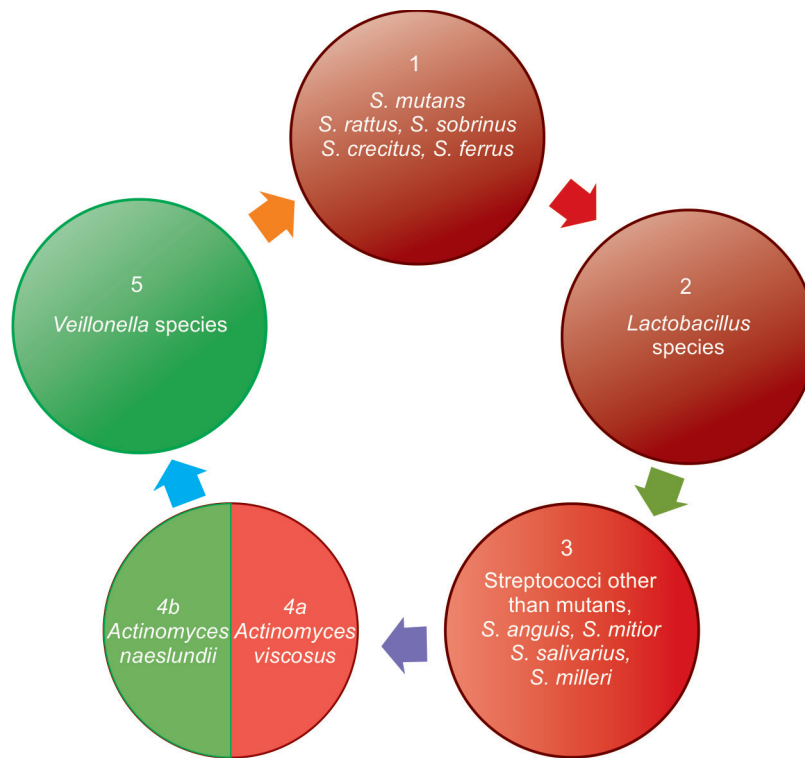

Figure 1 Microbiology of dental caries

Figures 2A and B (A) Pit and fissure caries; (B) Smooth surface caries

Figure 3 Nursing caries

Figure 4 Rampant caries

CLINICAL FEATURES

The common complaint with which the child is brought to a pediatric dentist is pain or swelling. Early sign detected is a white spot lesion. Here, the enamel surface is noncavitated but will become carious if demineralization continues. The child may have no pain in such lesions. Sensitivity and pain are features of the cavitated initial lesions. Deeper lesions show more pain and features of reversible pulpal damage. When infection progresses to affect the pulp, severe spontaneous and night pain will be present which suggests that pulp is irreversibly damaged. Infections crossing the root and spreading into bone can result in cellulitis and space infections (**Fig. 5**).

Figure 5 Space infection due to dental caries

APPROACH TO DIAGNOSIS

A major paradigm shift took place in the field of diagnosis of caries in 21st century. Earlier only cavitated lesions diagnosed with visual tactile examination were counted as decayed, whereas at present, even minimally demineralized lesions like white spot lesions detected with advanced diagnostic methods are counted as decayed.

MANAGEMENT

Early diagnosis of caries has resulted in two modes of treatment: nonoperative and operative. Nonoperative management is done in cases of early white spot and noncavitated lesions. This is done basically to arrest the progress of the lesion and to shift the environmental equilibrium toward remineralization so that more invasive operative treatment is avoided. The methods involved are maintenance of proper oral hygiene, use of antimicrobials, fluorides, remineralization agents and dietary control. Probably, the most important preventive method in early childhood caries (nursing or rampant caries) is dietary restriction. Instructions regarding feeding can be given to the mother (**Box 1**). Children's medicinal preparations for diseases like asthma, epilepsy, or fever are in syrup form with high sugar content. Vitamin supplements they regularly take at bedtime can be contributory to dental caries. Parents should

be informed about the effect the medicines can cause to the child's teeth and sufficiently motivated for the maintenance of oral hygiene after taking such medicines. Operative management involves use of different restorative materials. A lesion causing pulpal damage may have to be treated with endodontic treatment followed with a crown. Grossly decayed teeth may have to be extracted and a space maintainer provided to prevent space loss (**Fig. 6**).

CONCLUSION

A young child may often have a set of completely damaged teeth causing chronic severe pain so that he is unable to consume a proper diet resulting in malnutrition and even developmental delay due to lack of essential nutrients. Pediatricians, who are usually the first medical specialists to see such a child, are in a privileged position to give timely advice regarding feeding pattern and problems of night feeding (other than breastfeeding) which can go a long way in preventing debilitating childhood caries and associated problems.

IN A NUTSHELL

1. Dental caries is one of the most common chronic childhood diseases.
2. Dental caries, once established, always leaves a scar and can progress further leading to complications.
3. Many systemic diseases including cardiovascular diseases can get worse due to bacteremia from untreated lesions.
4. Night feeding (other than breastmilk) and its sequelae should be explained to the parents.
5. Pediatricians are often the first medical professionals to see a child, and in a position to give valuable suggestions to parents to prevent this dental disease.

Chapter 35.5

Recurrent Parotitis

Prakash Agarwal

Recurrent parotitis is defined as recurrent inflammation of one or both parotid glands. It is usually associated with swelling, pain, fever and redness. It is also known as juvenile recurrent parotitis or recurrent sialectatic parotitis. Recurrent parotitis is differentiated from suppurative parotitis by the inability to express pus from the parotid duct in recurrent parotitis.

EPIDEMIOLOGY

Recurrent parotitis has a male preponderance, and the peak age of onset is between 4 years and 6 years. Although rare, it is the most common inflammatory salivary gland disease in childhood after mumps. It presents with episodes lasting 4–7 days, approximately every 3–4 months. The disease is self-limiting usually resolves by adolescence, but a few cases may continue into adulthood. Mainly, the symptoms are seen to resolve after puberty.

ETIOLOGY

In vast majority of cases, its etiology is not known. Recurrent infection, allergy, congenital defects and genetic factors may play a role. Recurrent parotitis may be associated with Sjögren's disease and immune deficiency. As the age of onset increases, the diagnosis of Sjögren's disease is most likely. Certain viral infection like Epstein-Barr virus, parainfluenza virus, adenovirus, enterovirus, human herpes virus 6, enterovirus and parvovirus are implicated in recurrent parotitis. HIV-infected children are more prone to have persistent parotitis as part of the lymphoid interstitial pneumonitis complex. Recurrent parotitis may be associated with hypogammaglobulinemia, isolated IgG3 deficiency, and IgA deficiency. *Streptococcus viridans*, a mouth commensal, has also been implicated.

PATHOGENESIS

Its pathogenesis is still unknown. Decreased salivary flow may lead to stasis and cause damage to the ductules. The ductules may be abnormal from birth leading to inflammation and infection. Unilateral disease may be supported by pre-existing abnormality before the onset of clinical symptoms. Many asymptomatic glands had similar though often milder lesions. Most commonly mumps and other viral infections has been implicated but not proven to cause recurrent parotitis. According to Maynard, recurrent parotitis may be the end result of a sequence of events:

Initially, there is a low-grade inflammation of the gland and duct epithelium, due to low salivary flow rate due to dehydration and debility. This results in distortion and stricturing of the distal ducts, and metaplasia of the duct epithelium. The metaplasia results in excessive mucus secretion.

The histological picture includes lymphocytic infiltration around the intralobular ducts leading to damage of the duct wall reticulum, allowing extravasation of secretions into the gland parenchyma, and thus aggravating the inflammation.

CLINICAL FEATURES

It is characterized by intermittent swelling (**Fig. 1**) and redness of one or both parotid glands associated with pain, which can be very distressing. Overall condition of the patient may be good. The child

Figure 1 Parotid swelling

may have difficulty in mastication with coexisting fever. There may be signs of dehydration in severe parotitis. The saliva expressed from the Stensen's duct may be grainy and whitish compared to bacterial parotitis where it will be frank pus.

DIAGNOSIS

Suppurative bacterial parotitis, mumps, benign lymphoepithelial cysts and stone in the duct should be excluded. It is distinguished from suppurative bacterial parotitis by the absence of pus from the parotid duct.

Approach to Diagnosis

The diagnosis of recurrent parotitis is made on a clinical basis, and can often be confirmed by ultrasound, showing the classical features of sialectasis. Serum amylase may be elevated in acute parotitis. Sialogram may suggest multiple hypoechoic areas that correspond to the punctate pools. Histology may show periductal lymphocytic infiltration. Mutations of *SPINK-1* gene may predispose to juvenile parotitis. CT and MRI help to assess parotid tissue, along with MR sialography. Ultrasound scan has the advantage of being less invasive and can exclude stones, abscess and mass lesions. A normal ultrasound or sialogram does not exclude the condition. Sialendoscopy may be diagnostic and therapeutic. On scopy, the duct opening may be avascular and whitish compared to a normal opening, thereby confirming the diagnosis.

MANAGEMENT

Treatment may range from conservative measures to radiotherapy and total parotidectomy as in the past. As it is a relatively benign condition, conservative symptomatic treatment is recommended. Majority of the cases are viral in origin, and hence the role of antibiotics is doubtful. Nonsteroidal anti-inflammatory drugs (NSAIDs) are given to control pain and rarely fever. Sialogogic agents, warmth and massage and duct probing have been recommended. Ductal irrigation and dilatation may be possible by sialendoscopy. It gives a correct picture of the duct opening which is whitish and avascular compared to a normal duct. Intraductal irrigation with intraglandular hydrocortisone may give some relief. Surgical options are total parotidectomy in resistant cases, which is curative, but carries with it the inherent risks of nerve damage. Stensen's duct ligation with tympanic neurectomy may give some relief.

IN A NUTSHELL

1. Recurrent parotitis is presents with swelling, pain, fever and redness of parotid glands lasting 4–7 days, approximately every 3–4 months. It is also known as juvenile recurrent parotitis.
2. Recurrent parotitis is differentiated from suppurative parotitis by the inability to express pus from the parotid duct in recurrent parotitis.
3. Recurrent parotitis has a male preponderance, and the peak age of onset is between 4 years and 6 years.
4. Recurrent infection, allergy, congenital defects and genetic factors may play a role. Recurrent parotitis may be associated with Sjögren's disease and immune deficiency.
5. The disease is self-limiting, usually resolves by adolescence, but a few cases may continue into adulthood.

Chapter 35.6

Vomiting

Sumathi Bavanandam

Vomiting is a common problem in children and can occur in diseases involving many organ systems. Causes of vomiting vary from respiratory tract infection to more serious conditions like inborn errors of metabolism, central nervous tumors apart from gastrointestinal (GI) disease. A good history and thorough physical examination are important in identifying the underlying etiology and tailoring the investigations. Any child with prolonged vomiting (> 12 hours in a neonate, > 24 hours in children younger than two years of age, or > 48 hours in older children) should undergo appropriate investigations.

DEFINITIONS

- **Vomiting** Is an active process and involves the forceful expulsion of gastric contents through the mouth associated with contraction of the abdominal and chest wall musculature.
- **Regurgitation** Is a passive process in which food from the stomach is brought back into the mouth without abdominal and diaphragmatic muscular activity.
- **Rumination** This is a chewing and swallowing process of regurgitated food that has come back into the mouth which occurs within minutes of eating (or even during eating), through a voluntary increase in abdominal pressure.
- **Recurrent vomiting** At least three episodes of vomiting in a three-month period which may be chronic or cyclical.
- **Acute vomiting** Abrupt onset of short-term vomiting.
- **Cyclical vomiting syndrome (CVS)** Characterized by recurrent, discrete, self-limited episodes of vomiting and is defined by symptom-based criteria with negative laboratory, radiographic and endoscopic testing.
- **Psychogenic vomiting** There is no underlying organic cause. It is often chronic and is due to cortical or psychological input. Stressful events precipitate an attack and many children require hospitalization.

PATHOPHYSIOLOGY

The act of vomiting is a complex, coordinated autonomic response triggered by peripheral and central stimuli and involves neural, hormonal, and muscular responses generated by the reticular formation of the medulla with its several scattered groups of neurons. The vomiting center is located in the lateral medullary reticular formation of the brainstem and is the final pathway. The center has predominantly muscarinic (M1), histamine 1 (H1), neurokinin 1, and serotonin receptors and receives input from four distinct centers, namely chemoreceptor trigger zone, vagal afferent system, vestibular system and high cortical centers. Area postrema situated in medulla contains predominant D2 dopamine receptors and is unprotected by blood-brain barrier. As a result of this sampling of peripheral blood and cerebrospinal fluid, various metabolic and hormonal disorders can cause vomiting. Luminal distension or irritation of GI mucosa from various causes result in activation of vagal afferent system (mediated by serotonin receptors) and cause vomiting. In motion sickness and labyrinthine disorders, the vestibular system mediated via M1- and H1-receptors is involved in pathogenesis of vomiting.

The phases of vomiting are pre-ejection phase, a retching phase, and ejection phase. There is gastric relaxation and retrograde peristalsis in pre-ejection phase. During the phase of retching, there

is rhythmic contraction of respiratory, abdominal wall, intercostal, and diaphragm muscles against a closed glottis. In the final phase of ejection, there is intense contraction of the abdominal muscles along with relaxation of the pharyngoesophageal sphincter. These sequential events are not seen in projectile vomiting as in gastric outlet obstruction.

DIFFERENTIAL DIAGNOSIS

Vomiting is a symptom with a wide differential diagnosis, ranging from lesions of the GI tract to systemic illnesses, metabolic, endocrine, central nervous disorders to rare inborn errors of metabolism. Acute onset of vomiting with severe abdominal pain may suggest a surgical origin and is usually associated with localized or generalized abdominal tenderness, rigidity, absent or hyperactive bowel sounds. Causes of vomiting based on age are illustrated in **Table 1**. **Table 2** shows the *red flag signs* of vomiting.

EVALUATION

A detailed history, including diet, drug intake, family history, surgical history is important in the initial evaluation to identify a cause. History should include the following:

- Onset and type, whether acute, chronic or episodic
- Presence of nausea, headache, visual disturbances, photophobia, suggestive of migraine
- Previous history of surgery indicating adhesive obstruction
- Projectile vomiting without nausea suggestive of central nervous system (CNS) pathology
- Bilious vomiting to indicate a possible surgical cause (though it can occur in nonsurgical conditions)
- Presence of blood in the vomitus due to mucosal ulcerations, erosions or variceal bleed
- Feculent vomitus to indicate intestinal/colonic obstruction or gastrocolic fistula
- Presence of abdominal pain, food-related pain indicating peptic ulcer disease
- Stale food vomitus in gastric outlet obstruction
- Undigested food often seen in achalasia cardia, Zenker's diverticulum.

Physical Examination

Physical examination should focus on the following: Assessment of nutritional status, growth and development, assessment of hydration status, presence of anemia, icterus, abnormal odor, and abnormal neurological signs. Abdominal examination should include abdominal tenderness, absent or exaggerated bowel sounds, scars, hernia orifices. Presence of visible gastric peristalsis indicates gastric outlet obstruction. Complications of persistent vomiting include dehydration, electrolyte disturbances, acid-base imbalance and nutritional deficiency.

Investigations

These are indicated for: (1) bilious vomiting, abdominal tenderness and/or severe abdominal pain; (2) attacks precipitated by intercurrent illness, fasting, and/or high protein meal; (3) abnormalities on neurological examination including severe alteration of mental status, abnormal eye movements, papilledema, motor asymmetry, and/or gait abnormality (ataxia); and (4) progressively worsening episodes or conversion to a continuous or chronic pattern.

Tests include complete hemogram, liver function tests, renal functional tests, blood sugar, urine ketones to rule out diabetic ketosis, urine routine and culture, lactate, electrolytes, ammonia, ketones and arterial blood gas analysis for inborn errors of metabolism. A plain abdominal X-ray is useful to rule out

Table 1 Common causes of vomiting depending on age

Neonate (< 1 month)	Infant (> 1 – 12 months)	Toddler (> 1 – 4 years)	Child (4 – 12 years)	Teenager (13 – 19 years)
GER and GERD Feeding intolerance, pyloric stenosis, meconium ileus, malrotation with midgut volvulus, necrotizing enterocolitis, congenital atresia/webs, metabolic disorders, Hirschsprung disease, protein intolerance infection (UTI/meningitis)	GER or GERD Acute otitis media, protein intolerance, UTI, acute gastroenteritis, malrotation, volvulus, meningitis, CNS tumors, intussusception, metabolic disorders	Urinary tract infection, pharyngitis, GERD, celiac disease, intracranial lesion, malrotation, poisoning	Gastroenteritis, pharyngitis, postinfectious appendicitis, celiac disease, pancreatitis, IBD, poisoning/toxic ingestion Eosinophilic esophagitis	Gastroenteritis, peptic ulcer disease, cyclic vomiting, eosinophilic esophagitis, pregnancy, poisoning/toxic ingestion, migraine, diabetic ketoacidosis, drug abuse, appendicitis, gallstone, pancreatitis, bulimia, IBD

Abbreviations: GER, gastroesophageal reflux; GERD, gastroesophageal reflux disease; UTI, urinary tract infection; IBD, inflammatory bowel disease; CNS, central nervous system.

Table 2 Red flag signs with probable causes of vomiting

S. No.	Vomiting characteristics/associated features	Probable cause
1.	Failure to thrive or weight loss	GERD, obstructive GI diseases, metabolic causes, urinary causes
2.	Projectile vomiting, presence of abnormal neurological signs	CNS tumors, meningitis
3.	Localized abdominal pain: Right upper quadrant pain— Localized epigastric pain	Gallbladder disease esophagitis, peptic ulcer
4.	Hematemesis/melena	Esophagitis, esophageal ulcer, peptic ulcer, portal hypertension
5.	Severe dehydration with dyselektrolytemia	Serious underlying conditions, such as obstruction, CAH
6.	Bilious vomiting	Surgical causes Intestinal obstruction
7.	Short stature, anemia	Inflammatory bowel disease, hypothyroidism, or celiac disease
8.	Nocturnal vomiting, recurrent wheeze	Gastroesophageal reflux disease or postnasal drainage
9.	Fever, toxemia in young	Sepsis, meningitis
10.	Episodic vomiting with symptom-free interval	Cyclical vomiting syndrome

Abbreviations: GERD, gastroesophageal reflux disease; CAH, congenital adrenal hyperplasia; GI, gastrointestinal; CNS, central nervous system.

intestinal obstruction (**Fig. 1**); ultrasonography (USG) abdomen helps in diagnosis of hypertrophic pyloric stenosis, malrotation, intussusception, and obstructive uropathy. Barium contrast studies may be useful in gastroesophageal reflux disease (GERD), congenital esophageal stenosis (**Fig. 2**), achalasia cardia (**Fig. 3**), infantile hypertrophic pyloric stenosis (IHPS), duodenal web/atresia and intestinal narrowing. Upper GI endoscopy is useful in diagnosis of mucosal disease of upper GI tract (**Fig. 4**), *H. pylori* gastritis, eosinophilic esophagitis, and obstructive causes like strictures. Esophageal manometry helps in achalasia cardia and motility disorders of esophagus. CT brain/MRI is useful for identifying CNS tumors.

TREATMENT

Treatment depends on the underlying cause. A course of proton pump inhibitor (PPI) or histamine 2 receptor antagonist (H2RA) will benefit children with GERD. Avoidance of cow milk, thickening of feeds, and positioning will be of benefit. Infants and young children outgrow the problem by 1–2 years. Treatment options for eosinophilic esophagitis include acid suppression, corticosteroids (topical and systemic), and dietary modifications like elimination diet, like milk, soy, egg, peanut, wheat and fish or complete elemental diet. Stricture of esophagus secondary to eosinophilic esophagitis needs cautious endoscopic dilatation. Swallowed fluticasone (44–220 mg per swallowed puff) given as two puffs two times a day has been effective. Endoscopic stricture dilatation may be needed for peptic, corrosive and anastomotic strictures. Surgical management is indicated in IHPS/malrotation/intestinal atresia/web and intestinal obstruction. The recommended indications

of antiemetics are chemotherapy/radiation-induced vomiting, postoperative vomiting, cyclical vomiting and vomiting due to GI motility disorders.

CYCLICAL VOMITING SYNDROME

The exact etiology and pathogenesis of cyclical vomiting syndrome (CVS) still remain unclear. Girls are affected more than boys. Migraine variant, mitochondrial fatty acid oxidation disorders, GI motility disorder, disorder of the brain-gut axis, autonomic dysfunction, abdominal epilepsy, ion channel dysfunction, corticotropin-releasing factor in response to stress, altered psychodynamics, mitochondrial energy depletion due to mitochondrial mutation precipitated by stress/excitement are some of the proposed mechanisms that can trigger episodes of vomiting in children with CVS. The bilious vomiting is intense associated with disabling nausea and dehydration requiring hospitalization. Accompanying symptoms including pallor, listlessness, anorexia, nausea, retching, abdominal pain, headache and photophobia may make it difficult to distinguish episodes of CVS from other causes of acute abdomen and altered consciousness. Migraine, motion sickness, epilepsy, anxiety and depression are some of other observed associations of CVS. There are no specific laboratory markers to diagnose CVS. Since vomiting is often bilious and associated with pain, investigations need to be done to exclude organic causes.

Criteria for Diagnosis

- At least five attacks in any interval, or a minimum of three attacks during a 6-month period

Figure 1 Plain abdominal X-ray with multiple air fluid level in intestinal obstruction

Figure 2 Barium swallow showing long segment narrowing—congenital esophageal stenosis

Figure 3 Barium swallow in an infant showing dilated esophagus with smooth distal tapering suggestive of achalasia cardia

Figure 4 Upper gastrointestinal endoscopy showing severe esophagitis

- Episodic attacks of intense nausea and vomiting lasting 1 hour–10 days, occurring at least 1 week apart
- Stereotypical pattern and symptoms in the individual patient
- Vomiting during attacks occurs at least 4 times/hour for at least 1 hour
- Return to baseline health between episodes and not attributed to another disorder.

Treatment

During an acute attack, taking care of hydration and electrolytes is essential to prevent dehydration as well as in decreasing the duration of the acute illness. Ondansetron provides symptomatic relief. Sedation is usually beneficial during the episode. Avoidance of triggers such as fasting, intake of caffeine, chocolates are essential to avoid an attack. If the attack is more than one per month, prophylactic drug therapy is advisable. Propranolol has

been recommended as first-line prophylactic drug with good response in more than 85% of patients. Tricyclic antidepressants are effective in 68% of children with CVS. Phenobarbital, topiramate, and sumatriptan are other drugs that can be tried.

ABDOMINAL MIGRAINE

Abdominal migraine is defined as attacks of abdominal pain lasting for 1–72 hours, periumbilical or poorly localized, dull aching pain of varying intensity, usually accompanied with at least two of the following symptoms, namely anorexia, nausea, vomiting, and pallor. Thirty to forty percent of children can have associated headache. Family history of migraine can be documented in a subset of children. Vascular constriction causing ischemia of GI tract or CNS areas innervating the gut may be the cause. Clinical history, physical examination and investigations are essentially normal. Prophylactic use of propranolol can be useful.

IN A NUTSHELL

1. Vomiting is a symptom of a variety of disorders ranging from self-limited diseases to life-threatening diseases, and the treatment depends on the etiology apart from symptomatic therapy.
2. Good history and thorough physical examination are crucial to early identification of serious conditions.
3. Copious bilious emesis at any age is a sign of intestinal obstruction until proven otherwise.
4. Cyclical vomiting is not an uncommon cause of chronic recurrent episodic vomiting in older children and adolescents.
5. Presence of *red flag* signs and symptoms requires thorough evaluation and urgent attention.

Chapter 35.7

Infantile Hypertrophic Pyloric Stenosis

Ketan Parikh

It is characterized by persistent nonbilious vomiting in a neonate and may lead to significant dehydration and metabolic disturbances if not diagnosed early enough. It was earlier believed that the condition is relatively rare in India; however, a relatively higher incidence is being reported in recent times. Most cases are sporadic but few cases may run in families. Boys (mostly first-born) are five times more commonly affected than girls.

PATHOLOGY

Musculature of the pyloric antrum is significantly hypertrophied, thus the pylorus is thickened and the pyloric canal is lengthened and narrowed. The hypertrophied pyloric muscle becomes olive-shaped and becomes hard to feel when contracted. This hypertrophied pylorus is clinically palpable as a 'pyloric tumor'. The stomach proximal to the obstruction is dilated and is also secondarily hypertrophied.

Gastric mucosa in infancy produces a potent lipase which hydrolyses milk to free fatty acids. The hypertrophied pyloric muscle leads to a partial obstruction to the outflow from the pylorus. Thus there is stagnation of milk in the stomach. Rancidity of the curdled milk gradually causes progressive mucosal edema and precipitates complete obstruction of the narrowed and hypertrophied pyloric canal (**Fig. 1**) and thus symptoms are often delayed till 3–6 weeks.

CLINICAL FEATURES

Usually the child presents between 3 weeks and 6 weeks but the child may present anytime from 1 week to 4 months. Progressive, forcible, projectile and nonbilious vomiting is the most important presenting symptom. The vomitus may contain altered blood. The baby is usually very hungry after vomiting. There is associated weight loss or failure to gain weight. Constipation occurs due to poor intake. Jaundice is occasionally seen due to nutritional deficiencies. Facies is characteristic—alert, anxious and hungry look. These patients have a slow and shallow breathing due to the metabolic alkalosis secondary to persistent vomiting. Examination is characterized by visible gastric peristalsis on inspection (left to right) (**Fig. 2**). Examination must be done with the child comfortably placed in the mother's lap and in good light. Palpation of the "tumor" (palpable in 70% cases) is the diagnostic sign. It should be sought for with the left hand, sitting on the patients' left palpating below the right costal margin, below the liver border.

Figure 1 Pyloric muscle thickening (hollow arrow) causing partial obstruction and residue (R), causing mucosal edema (M) and resultant complete obstruction (block arrow)

DIAGNOSIS

Infantile hypertrophic pyloric stenosis (IHPS) needs to be differentiated from other causes of nonbilious vomiting in young infants: gastroenteritis; septicemia, meningitis, intracranial hemorrhage; gastroesophageal reflux, and achalasia cardia. USG shows the thickened pylorus and may also show reverse peristalsis on the stomach. Contrast studies with Barium (only if necessary) reveal a large stomach, delayed emptying, string sign, and gastritis (**Fig. 3**). Serum electrolytes and blood gas reveal hypokalemic hypochloremic alkalosis.

TREATMENT

Surgery is the treatment of choice. Nonsurgical treatment with prokinetics should be tried only in case of strong contraindication to surgery as the treatment has erratic results, is too prolonged and may lead to aspiration and malnutrition.

Preoperative correction of metabolic disturbances is an integral part of the surgical treatment and usually is achieved within 24 hours. Aggressive resuscitation can produce rapid fluid and electrolyte shifts, possibly leading to seizures. Correct dehydration and electrolyte imbalance. Aspiration of the gastric contents may help in reducing the gastric mucosal edema. If necessary a gastric lavage with normal saline would help. Oral rehydration with 0.33% or 0.5% dextrose saline with 20–40 mEq/L

Figure 2 Visible peristalsis (L → R) seen in a quiet child after feeding

Figure 3 String sign on upper gastrointestinal (GI) series

of potassium may help once the mucosal edema regresses within a few hours and this avoids the possible complications of rapid IV rehydration. Alternatively IV rehydration with 0.33% saline and appropriate potassium correction may be resorted to. Fredet-Ramstedt's pyloromyotomy is the desired procedure; which can be achieved by open or laparoscopic (**Fig. 4**) approach. The results are excellent with a low incidence of complications.

Figure 4 Laparoscopic view of hypertrophied pylorus, maybe palpable like an olive

IN A NUTSHELL

1. IHPS should be suspected in any infant with persistent non-bilious vomiting.
2. Presence of visible gastric peristalsis (left to right) should increase this suspicion.
3. Ultrasonography is now the investigation of choice in the diagnosis of IHPS.
4. Serum electrolytes and blood gas reveal hypokalemic hypochloremic alkalosis.
5. Fredet-Ramstedt's pyloromyotomy is the desired treatment of choice.

Chapter 35.8

Gastroesophageal Reflux

Elsie Jazmin Foglio, Dinesh S Pashankar

Gastroesophageal reflux (GER) is one of the most common disorders of the esophagus in the pediatric age group. It can be defined as spontaneous and effortless passage of gastric contents from the stomach into the esophagus. GER may be physiological as seen in infancy or pathological. Gastroesophageal reflux disease (GERD) usually implies the presence of significant clinical symptoms due to pathological reflux and complications.

EPIDEMIOLOGY

Gastroesophageal reflux is common in infancy worldwide and usually presents as vomiting or regurgitation. In a population-based study involving 602 infants from New Delhi, the prevalence of regurgitation was noted to be 55% in infants between 1 month and 6 months of age and the prevalence dropped to 15% in infants between 7 months and 12 months. The prevalence of GER decreases with age in children, but increases again in adolescence. In a study from USA, symptoms of reflux in the form of heartburn and regurgitation were reported in about 2% of 3–9-year-old children and about 5–8% of 10–17-year-old children.

There are certain groups of children who are at high-risk for severe reflux and GERD. These include children with neurological impairment such as cerebral palsy and children who have had surgery for esophageal atresia. Obesity, presence of hiatal hernia, and chronic respiratory disorders are also predisposing factors for severe GER in children.

PATHOPHYSIOLOGY

Transient relaxation of the lower esophageal sphincter (TRLES) is defined as abrupt, prolonged (> 10 sec) and complete relaxation of the lower esophageal sphincter (LES). It occurs independent of swallowing and is the most frequent mechanism causing GER in children and adults. This inappropriate relaxation of LES tone allows gastric contents to enter the esophagus, thus exposing the esophageal mucosa to the acidic gastric contents.

Recurrent acid reflux can injure the distal esophageal mucosa resulting in esophagitis. Chronic esophagitis may lead to complications such as stricture or Barrett's esophagus, which may subsequently result in adenocarcinoma of esophagus. Fortunately, this complication is very rare in children. GER can cause respiratory complications either due to aspiration or reflex bronchospasm. Reflux of acid into the larynx may cause irritation leading to laryngitis or apnea.

CLINICAL FEATURES

Gastroesophageal reflux in infancy is physiological and presents as regurgitation or spitting. Weight gain is excellent and there is no evidence of complications such as esophagitis or respiratory symptoms. These infants are aptly called "happy spitters". The physiological reflux of infancy generally begins in the first few weeks of life, peaks at about 6 months and usually resolves by 8–12 months of age.

As opposed to physiologic reflux of infancy, GER in older children can be significant and lead to GERD. **Table 1** shows symptoms and the spectrum of complications of GER. Esophagitis is one of the most common complications of GER in children and usually presents with epigastric pain or hematemesis.

However, irritability with feeds or feeding refusal may be the only manifestation of esophagitis in younger children or neurologically impaired patients. Reflux esophagitis is being diagnosed more frequently in Indian children with the use of endoscopy. In a study from Lucknow, reflux esophagitis was diagnosed in 26 of 33 children who presented with symptoms suggestive of reflux. In the same study, other complications of reflux such as esophageal stricture, Barrett's esophagus and respiratory symptoms were also observed in Indian children.

There are a number of studies reporting an association between reflux and upper and lower respiratory symptoms in children. However, a clear etiologic role of reflux causing dental, ear, nose, throat and respiratory complications is not confirmed. The clinical association of bronchial asthma and GERD is well known although convincing causal relationship has not been established. *Waterbrash*, the sudden appearance of sour salty fluid in the mouth secondary to hypersecretion of the salivary glands in response to the presence of acid in the esophagus, may be seen in older children with GER. Some infants with severe GERD may present with failure to thrive secondary to frequent copious vomiting, and refusal of food due to the pain of esophagitis. Apnea in infants due to laryngospasm caused by nasopharyngeal microaspiration, and sudden infant death syndrome (SIDS) may be manifestations of GERD.

Sandifer syndrome is a rare complication of GERD. It is an unusual movement disorder characterized by spasmodic torsional dystonia with arching of the back and opisthotonic posturing. Hence, it may be mistaken for seizure disorder.

DIFFERENTIAL DIAGNOSIS

Differential diagnosis of chronic vomiting is wide and is discussed elsewhere in this book. In young infants with severe vomiting, pyloric stenosis and malrotation should be considered and ruled out. In older children, acid peptic diseases such as gastritis or ulcer can present with vomiting and epigastric pain. Eosinophilic esophagitis, a condition more common in the Western World, can present with vomiting, epigastric pain and dysphagia. Neurological causes should be considered in children presenting with chronic vomiting and headaches.

APPROACH TO DIAGNOSIS

The diagnosis of GER can be made in many children based on history and physical examination. Particularly, a detailed history is all that is necessary to diagnose physiological reflux of infancy. In a growing infant who is otherwise well, daily vomiting of small volume is suggestive of physiologic reflux and no further investigations are necessary. The diagnostic criteria of infant regurgitation according to Rome III classification include regurgitation of two or more times per day for 3 or more weeks in otherwise healthy infants (3 weeks to 12 months of age) without retching, hematemesis, aspiration, apnea, failure to thrive, feeding or swallowing difficulties, or abnormal posturing. Infant questionnaire developed by Orenstein et al. has 11 questions which can be used to differentiate GER from GERD with high sensitivity and specificity (74% and 94%) in USA. However, when applied to Indian infants, this questionnaire had low sensitivity and specificity (43% and 79%) and has low diagnostic utility.

In older children, heartburn and regurgitation are the usual symptoms of GER. A careful history should be obtained to assess for GER and complications as shown in **Table 1**. It is important to determine the presence of predisposing risk factors, as mentioned above, as these children are likely to have severe reflux disease and require investigations and long-term therapy.

There are various diagnostic studies to assess reflux and complications and are shown in **Table 2**. There is no single test to assess GER in children and tests should be planned depending

Table 1 Symptoms and complications of gastroesophageal reflux

<i>Reflux</i>	<i>Lower respiratory tract*</i>
Vomiting	Bronchospasm, wheeze
Regurgitation	Chronic cough
Heartburn	Recurrent pneumonia
<i>Esophagitis</i>	<i>Upper respiratory tract *</i>
Feeding refusal, irritability	Laryngitis, hoarseness
Heartburn, epigastric pain	Obstructive apnea
Hematemesis	Dental erosions
Anemia	Sinusitis
<i>Esophageal stricture</i>	<i>Neurological</i>
Dysphagia	Sandifer's syndrome

* Possible association.

Table 2 Diagnostic studies for GER and complications

<i>Tests</i>	<i>Diagnostic utility</i>
Upper gastrointestinal series	<ul style="list-style-type: none"> To assess anatomical abnormalities To rule out malrotation, hiatal hernia, stricture
24-hour esophageal pH study	<ul style="list-style-type: none"> To detect acid reflux in the esophagus To correlate acid reflux and extraesophageal manifestations
Endoscopy with histology	<ul style="list-style-type: none"> To diagnose esophagitis, Barrett's esophagus To rule out gastritis, peptic ulcer, eosinophilic esophagitis To dilate esophageal stricture
Impedance study	<ul style="list-style-type: none"> To detect acid and nonacid reflux in the esophagus To correlate acid and nonacid reflux and extraesophageal manifestations

on the clinical presentation of the child. Upper gastrointestinal barium study is not a good test to diagnose reflux because of poor sensitivity and specificity, but it is useful to rule out anatomical abnormalities. Twenty-four hour esophageal pH study is useful to assess acid reflux in the esophagus. The test is performed by the transnasal placement of a standardized microelectrode into the lower esophagus, for continuous measurement and recording of intraesophageal pH for 24 hours. An episode of acid reflux is usually defined as an esophageal pH less than 4. Computerized analysis calculates the number, duration of reflux episodes and reflux index. The reflux index (percentage of time esophageal pH is less than 4) of more than 5% and 10% are suggestive of GER in children and infants respectively. The pH study is particularly useful to look for acid reflux in children with extraesophageal symptoms and to assess adequacy of acid suppression. Multichannel Intraluminal Impedance (MII) is a procedure that measures change in electrical resistance (impedance) between multiple electrodes located on an esophageal catheter. It is done with pH monitoring and can detect acid and nonacid reflux. MII can be useful for correlation of (acid and nonacid) reflux and symptoms such as apnea, cough and respiratory symptoms. However, the test is expensive and is not readily available.

Endoscopy with histology can determine the presence and severity of esophagitis, strictures and Barrett's esophagus. It is also useful to rule out other conditions such as eosinophilic esophagitis and acid peptic disease including gastritis or peptic ulcers which may present with similar symptoms as GERD. Therefore, endoscopy has become the test of choice for children with reflux

symptoms in many centers in USA. At endoscopy, erosions or ulcers of distal esophagus indicate severe esophagitis. Histological criteria of reflux esophagitis include presence of eosinophils, basal zone hyperplasia and increased papillary length.

There are other tests to assess GER and complications, but are not used routinely. Gastric scintigraphy is a nuclear medicine scan used to assess gastric emptying and reflux of nonacidic gastric contents. A lack of standardized technique and absence of age specific normative data limit the value of this test. Bronchoscopy may show lipid-laden macrophages suggestive of pulmonary aspiration secondary to reflux.

In adults, an empiric trial of proton pump inhibitor (PPI) is routinely used. Although not well studied in children, empiric trial of PPI for up to 4 weeks is justified in older children with classical symptoms of GERD such as heartburn or regurgitation. However, a long-term PPI therapy without a specific diagnosis is not recommended.

MANAGEMENT

For physiologic reflux of infancy, reassurance to parents is the most important part of the management as reflux improves with time and without any intervention. Smaller and more frequent feeds are beneficial in infants with GER. Frequent burping during feeds as well as keeping infants in an upright position after feeding is recommended. Thickening of formula feeds with rice cereal can decrease the number of episodes of vomiting in infants. Acid suppression medications can be used, but are not recommended. Therapeutic strategies for the management of GER in older children are shown in **Table 3**.

General Measures

Elevation of the head of the bed is recommended for older children with nocturnal reflux symptoms. Children should be advised to avoid acidic fruit juices, caffeinated beverages, chocolate and fatty foods as these tend to make reflux symptoms worse. Exposure to smoking can also worsen reflux symptoms and therefore should be avoided. Weight loss is beneficial in obese children with reflux.

Acid Suppression Therapy

It is commonly used as first line therapy for significant reflux. Antacids directly buffer gastric acidic contents and reduce heartburn and reflux symptoms. They can be used on as needed

Table 3 Therapeutic strategies for gastroesophageal reflux (GER)

Lifestyle changes	<ul style="list-style-type: none"> Positioning Avoidance of smoking exposure Weight reduction in obese children Dietary changes
Antacids	<ul style="list-style-type: none"> Aluminum hydroxide/magnesium carbonate 10–20 mL as needed Aluminum hydroxide/magnesium hydroxide 10–20 mL as needed

Abbreviations: H₂RAs, histamine 2 receptor antagonists; PPI, proton pump inhibitor.

basis, but regular long-term use is not recommended. Acid suppressants such as histamine 2 receptor antagonists (H₂RAs) and proton pump inhibitors (PPIs) act to decrease esophageal acid exposure by reducing the quantity of gastric acid secretion. H₂RAs block histamine receptors on the parietal cell while PPIs block the Na-K-ATPase enzyme (proton pump), which is the final common pathway of acid secretion. While both H₂RAs and PPIs are effective in the healing of esophagitis and symptomatic relief of reflux symptoms, PPIs are superior to H₂RAs. PPIs should be given 30 minutes before breakfast to get maximum efficacy. The duration of therapy should be 3–6 months and an attempt should be made to withdraw these medications after that time.

Flow chart 1 shows algorithm for treating children with GER symptoms who have no risk factors for chronic GERD. High-risk group of children often require long-term therapy for months to years for ongoing severe GERD. In children with GERD and asthma, chronic cough can predispose to reflux and reflux can cause reflex bronchospasm. Therefore, it is prudent to treat both conditions simultaneously for symptomatic relief. Adverse effects related to H₂RA and PPIs are generally mild and rare. They include headache, diarrhea and constipation. Tachyphylaxis can develop with H₂RAs and therefore they should not be used for long-term therapy. PPIs are generally well tolerated over long-term (up to 11 years). Some patients taking them for prolonged periods may develop mild to moderate hypergastrinemia. Even though gastric carcinoids have been shown in some animal studies, they have not been shown in humans. The secretion of intrinsic factor is also inhibited along with that of acid. However, megaloblastic anemia due to vitamin B₁₂ deficiency is rare, which reflects the large stores of the vitamin in the body.

Prokinetic Agents

Metoclopramide (dopamine-2 and 5-HT₃ antagonist), domperidone (D₂ receptor antagonist), cisapride, mosapride and renzapride (selective 5HT₄ agonists) and erythromycin (motilin receptor agonist) are commonly used in adults with GERD to improve esophageal motility and gastric emptying. However, they

cannot decrease TRLES which plays a key role in the pathogenesis of GER. Cisapride may cause QT prolongation, arrhythmia and Torsades de pointes, and has been withdrawn from many countries. Hence, prokinetic agents are not recommended currently in children due to their doubtful efficacy and risk of adverse effects.

Other Drugs

The selective GABA agonist *baclofen*, which is used in children with spasticity, inhibits TRLES, and is hence useful in GERD. It also reduces postprandial acid and nonacid reflux and its associated symptoms. However, it may cause fatigue, confusion and insomnia and there are only very few studies in children. Drugs like salbutamol, theophylline, diazepam and barbiturates, which can precipitate or aggravate reflux should be avoided in children with GER.

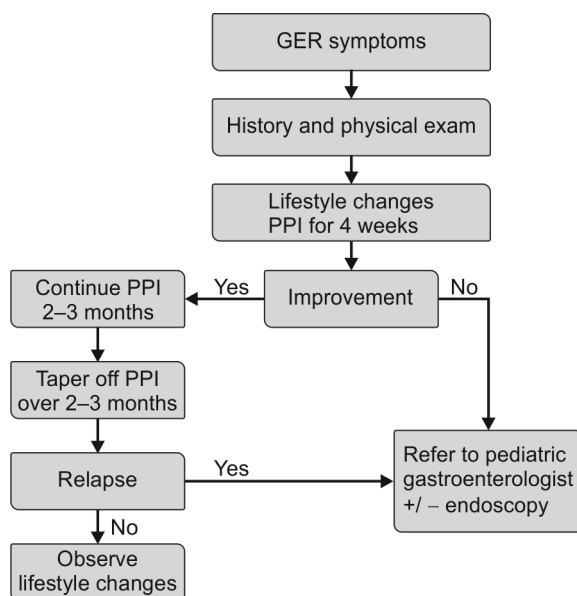

Surgical Therapy

It is indicated for intractable reflux despite medical management and life-threatening aspiration. The most common procedure is fundoplication in which a part of stomach is wrapped around the lower esophagus to prevent reflux. Nissen fundoplication is the most common operation performed. Fundoplication has a high success rate in the otherwise normal children with reflux. However, in a high-risk group of children with severe GERD, fundoplication is associated with a significant rate of failure and complications. In this group of children PPIs have been shown to be effective, even after failure of fundoplication. Recently laparoscopic fundoplication has been gaining popularity due to shorter postoperative stay. Overall, with the availability of proton pump inhibitors, necessity of fundoplication has decreased considerably.

PROGNOSIS

Physiologic reflux of infancy usually does not need any major therapeutic intervention and has excellent prognosis. Children with GERD respond well to dietary advice and PPI therapy. Children in high-risk group can develop severe GERD and complications and often require combination of long-term PPI therapy and surgery.

Flow chart 1 Approach to GER in older children

Abbreviations: GER, gastroesophageal reflux; PPI, proton pump inhibitor.

IN A NUTSHELL

1. Gastroesophageal reflux is common in infancy and disappears by 1 year of age in most cases.
2. Gastroesophageal reflux of infancy is diagnosed by history and does not require any tests or major therapeutic intervention.
3. Children with neurologic impairment, chronic respiratory disorders, obesity and history of repaired esophageal atresia are at high-risk for developing severe GERD.
4. Gastroesophageal reflux in older children presents as vomiting, regurgitation and heartburn.
5. Gastroesophageal reflux can lead to esophagitis and may be associated with asthma and other respiratory complications.
6. Esophageal pH study and impedance study can be helpful to assess correlation of GER and extraesophageal symptoms.
7. Endoscopy with histology is the best test to diagnose esophagitis.
8. Acid suppression with H₂RA and PPI are effective in healing esophagitis and providing symptomatic relief.
9. Children with high-risk for GERD require a long-term PPI therapy.
10. Surgery for GERD is reserved for severe aspiration or failure of medical therapy.

Chapter 35.9

Umbilical Hernia

Prakash Agarwal

Umbilical hernia is herniation of the intestine through the umbilical ring (**Fig. 1**). Umbilical hernia is commonly seen in infants, which may herald an underlying problem or in most of the cases may be just a routine finding and settles down on its own.

EPIDEMIOLOGY

Umbilical hernia in children has an equal frequency in boys and girls. A slightly higher incidence is reported in Africa and African-American infants. The incidence is around 75% in low birthweight infants, which will spontaneously close over time. The incidence is higher in patients with Down syndrome, Trisomy 18, Trisomy 13, mucopolysaccharidosis, and congenital hypothyroidism. It may also be a part of Beckwith-Wiedemann syndrome.

ETIOLOGY

Defect in the underlying fascia below the umbilical ring leads to an umbilical hernia.

PATHOGENESIS

During development of the fetus the umbilical cord passes into the abdomen through the umbilical ring. After birth, the opening in the abdominal muscles closes as the baby matures. Sometimes, these muscles do not meet and grow together completely, and there is still a small opening present. A loop of intestine can move into the opening between abdominal muscles and cause a hernia.

An umbilical hernia in children is surrounded by a dense layer of fascia through which a peritoneal sac attached to the overlying skin protrudes; this is known as direct umbilical hernia. Usually the umbilical ring continues to close over time and the fascia of the umbilical defect strengthens, which accounts for the spontaneous resolution of this defect in most children. An indirect umbilical hernia is one in which the peritoneal contents herniate superior to the umbilical ring. The hernia follows the umbilical canal along the umbilical vein, the linea alba anteriorly, and a thin layer of preperitoneal fascia in a posterior direction. This form of hernia is

also known as proboscoid hernia (**Fig. 2**). Hernia of the umbilical cord is one in which there is a defect in the peritoneum and the fascia leading to intestine herniating into the substance of the umbilical cord (**Fig. 3**).

CLINICAL FEATURES

Umbilical hernias do not usually cause pain. They are present at birth but may become more noticeable when the child is bearing down—crying, coughing, or straining to have a bowel movement. The bulge may seem to disappear when the child is quiet or resting. Umbilical hernia with a small ring diameter (< 1.0 cm) is more likely to close spontaneously and earlier than those with a ring diameter of more than 1.5 cm. Incarceration of intestine or omentum, strangulation, perforation, evisceration and pain are rare events in the natural history in the umbilical hernia of children.

MANAGEMENT

Umbilical hernia is a clinical diagnosis and usually does not require any investigations to confirm the diagnosis. Routine blood investigations are required before proceeding for surgery in order to rule out anemia and bleeding profile. A thyroid profile may be

Figure 2 Proboscoid umbilical hernia

Figure 1 Typical presentation of an umbilical hernia

Figure 3 Hernia of the umbilical cord

done to rule out congenital hypothyroidism. An ultrasound may be done to rule out intra-abdominal tumors or ascites.

Indications for surgery We usually observe umbilical hernia and manage conservatively till 2 years of age. Rare event of incarceration requiring reduction, strangulation, perforation, evisceration are absolute indications for surgery. Infant with giant proboscoid hernia in whom the umbilical ring does not narrow may be considered for repair before 2 years. Typical umbilical hernia should be observed until the age of 2 years. Sometimes the most difficult task is to convince the family that observation alone will be successful in most cases and that the hernia may resolve spontaneously by 2 years of age. If the child has an obstructed umbilical hernia it is reduced by milking the air out of the incarcerated loop of intestine and applying firm pressure on the mass. One episode of obstruction should prompt the surgeon to operate immediately. If reduction is not possible then emergency surgery is required. If an infant is having both inguinal and umbilical hernia, the umbilical hernia should be left alone as it may close spontaneously.

Surgery for umbilical hernia Standard procedure for umbilical hernia repair involves multilayer closure of the peritoneum and fascial layer. A small curved incision (resembling a smile) will be made under your child's belly button. Absorbable and nonabsorbable sutures are used in the repairs. The redundant skin may be left in place to resolve over a period of time. Usually repair of umbilical hernia is performed as a day care surgery after infiltrating the wound with local anesthesia. Complications of umbilical hernia repair may be infection of the repaired wound, recurrence of the hernia and rarely visceral injuries.

After surgery, the child's umbilicus may appear to be slightly swollen, but this will resolve over the next few weeks. The child should be advised not to participate in physical education or sports for 2–3 weeks after surgery.

IN A NUTSHELL

1. Umbilical hernia is herniation of the intestine through the umbilical ring.
2. Umbilical hernia may be of three types, an indirect umbilical hernia, proboscoid hernia and hernia of the umbilical cord.
3. Incarceration of intestine or omentum, strangulation, perforation, evisceration and pain are rare.
4. Umbilical hernia with a small ring diameter (< 1.0 cm) is more likely to close spontaneously and sooner than those with a ring diameter of more than 1.5 cm.
5. Umbilical hernia is a clinical diagnosis and usually doesn't require any investigations for confirmation of the diagnosis.
6. Indications for surgery in umbilical hernia are, umbilical hernia not resolving spontaneously by 2 years, proboscoid hernia and incarcerated umbilical hernia.

Chapter 35.10

Constipation

Praveen Kumar, Preeti Singh

Constipation is a feeling of unsatisfactory defecation—hard stools, passage of too small stools or too difficult to expel. North American Society of Pediatric Gastroenterology, Hepatology and Nutrition has defined chronic constipation as *delay or difficulty in defecation present for 2 or more weeks which causes significant distress to the patient*. If inadequately treated, it may lead to chronic abdominal pain, loss of appetite, and fecal incontinence. In addition, it can also make the child under confident and socially secluded. Constipation is generally under-reported because of lack of lucid definition and embarrassment to seek medical advice. The reported prevalence varies from 0.3% to 30%, depending upon the definition used in the study.

NORMAL PHYSIOLOGY

There is a wide variation in stool according to age and diet. Some breastfed infants may defecate after each feed, while others may have infrequent soft bowel movements (2–14 days). In infants and young children defecation is a simple spinal reflex and social training brings control of the reflex by higher centers. Most children achieve voluntary control of stool by the age of 2–3 years. Bowel continence is primarily maintained by internal and external anal sphincters. The involuntary internal anal sphincter which is the thickened circular smooth muscle at the levator ani flexure, receives innervations from parasympathetic splanchnic nerves (inhibitory) and sympathetic (excitatory) nerves. Internal sphincter relaxes when the rectum gets distended. The external anal sphincter which is under voluntary control consists of somatic skeletal muscle innervated by the pudendal nerve. It is maintained in a state of tonic contraction unless the person has the desire and the place is conducive. Another important anatomical landmark is puborectalis muscle which makes a sling around the lower part of rectum. Puborectalis gets inserted into symphysis pubis and is responsible for maintaining the normal anorectal angle of 85–100 degree. During defecation, this angle becomes straight or obtuse in squatting position to ensure smooth passage of stool. Rectal distension with feces initiates reflex contractions of its musculature with initiation of the desire to defecate. Subsequently voluntary defecation is initiated by relaxation of the external anal sphincter with expulsion of the rectal contents. Difficulties with defecation result from dysfunction in any part of the normal anatomy or physiology of defecation.

PATHOPHYSIOLOGY

The desire to defecate is activated when stool comes into contact with lower rectal mucosa. In the absence of favorable environment to defecate, there is failure of relaxation of the external anal sphincter and feces keep getting accumulated higher in the rectal vault further abolishing the defecation reflex. With progressive stool accumulation over a period of time, the rectum dilates leading to loss of sensation and effective propulsive movements required for evacuation. The retained stools become harder and difficult to pass causing painful defecation and development of anal fissure. This further reinforces stool withholding behavior, thus leading to a vicious cycle. The retentive posture is an attempt to avoid defecation in which the infant typically screams with facial flushing, exhibit stiffening of the body with arching of back and contraction of gluteal muscles. Similarly toddlers and older

children stand straight and stiff, or hold onto furniture, cross their legs, walk on tiptoes to withhold stools till the defecation urge passes off. These signs are often misinterpreted by parents as straining to pass stools. If this persists for a long duration, watery stools may leak around the large fecal mass causing involuntary soiling or encopresis.

DEFINITIONS

Functional constipation The Rome III criteria for diagnosis of functional constipation depends on the age of the child and is given in **Box 1** and **2**.

Encopresis Encopresis is the involuntary passage of formed, semi-formed or liquid stool in the child's underwear after achieving age of continence. This may be a complication of chronic constipation.

Intractable constipation Constipation not responding to optimal conventional management given for 3 months.

ETIOLOGY

Organic causes accounts for only 5–10% cases, but there are a large number of conditions which can cause constipation (**Box 3**). Constipation is labeled as functional or idiopathic when it cannot be explained by organic causes. Functional constipation is responsible for 90–95% of chronic constipation in children. The most common organic cause in young children is Hirschsprung disease (HD) accounting for 6% of all patients.

Functional constipation during childhood is a result of a complex interplay of developmental transitions, environmental factors and parental response. Retention of stools starts in response to a number of relatively innocent events like voluntary retention to avoid school toilets, protest against bowel training, diet lacking fiber or temporary illness, anal fissure, etc. If an acute episode of constipation is not managed appropriately, it leads to chronic constipation.

BOX 1 The Rome III criteria for functional constipation in neonates and toddlers*

- < 2 defecations per week
- > 1 episode per week of incontinence after the acquisition of toileting skills
- History of excessive stool retention
- History of painful or hard bowel movements
- Presence of a large fecal mass in the rectum
- History of large-diameter stools that may obstruct the toilet
- For a child with a developmental age < 4 years, at least 2 of the above symptoms must occur for at least 1 month.

* Hyman PE, Milla PJ, Benninga MA, et al. Gastroenterology. 2006;130:1519–26.

BOX 2 The Rome III criteria for functional constipation in children and adolescents*

- Two or fewer defecations in the toilet per week
- At least one episode of fecal incontinence per week
- History of retentive posturing or excessive volitional stool retention
- History of painful or hard bowel movements
- Presence of a large fecal mass in the rectum
- History of large diameter stools that may obstruct the toilet.
- For a child with a developmental age > 4 years with insufficient criteria for irritable bowel syndrome, ≥ 2 criteria fulfilled at least once/week for at least 2 months before diagnosis.

* Rasquin A, Di Lorenzo C, Forbes D, et al. Gastroenterology. 2006;130:1527–37.

BOX 3 Etiology of constipation

- **Functional constipation** (85–95%)
- **Organic causes** (5–15%)
 - *Abnormalities of colon and rectum*
 - Chronic intestinal pseudo-obstruction
 - Pelvic or sacral mass
 - Anal stenosis
 - Anal or colonic stricture—post NEC or IBD
 - Postsurgical repair of imperforate anus
 - Anteriorly placed anus
 - *Neuropathic lesions of the gastrointestinal tract*
 - Hirschsprung disease
 - Intestinal neuronal dysplasia
 - *Spinal cord lesions*
 - Spina bifida
 - Meningomyelocele
 - Sacral agenesis
 - Diastematomyelia
 - Spinal cord tumors (lipomas, cysts)
 - *Metabolic causes*
 - Diabetes mellitus
 - Diabetes insipidus
 - Hypothyroidism
 - Hypercalcemia/hypocalcemia
 - *Neurologic causes*
 - Cerebral palsy, autism
 - *Drugs*
 - Analgesics, antacids, anticholinergics, lead toxicity
 - Bismuth, iron, cholestyramine, psychotropics
 - *Others*
 - Celiac disease, cystic fibrosis, cow milk protein allergy.

Abbreviations: NEC, neonatal necrotizing enterocolitis; IBD, inflammatory bowel disease.

CLINICAL PRESENTATION

Although many children are brought with difficulty in defecation or infrequent bowel movements, others present with a variety of symptoms like recurrent abdominal pain, vomiting, abdominal distension, abdominal mass, blood-streaked stools or excessive flatulence. Infants and toddlers may present with irritability. Mothers may sometimes give history of straining while passing stools, posturing (squeezing of buttocks, scissoring or crossing of their legs) with some children even having loose stools from encopresis.

EVALUATION

A thorough history and physical examination (**Table 1**) is essential for differentiating functional constipation from an organic cause. Examination of the perineum and perianal area is important. Abdominal examination may reveal a lump in the left iliac fossa or suprapubic area due to retention of fecal matter in the sigmoid and descending colon. Development and psychological history (interaction with siblings and peers, temperament, any disruption of family life) helps in identifying underlying cause. Family history of chronic gastrointestinal diseases like inflammatory bowel disease, irritable bowel syndrome should also be enquired.

The *Red Flags Signs*, helpful in identifying an organic disease are given in **Table 2**. One of the most important organic causes of constipation during neonatal period is HD. Important clinical pointers in an affected infant include abdominal distension, pencil—thin hard pellet like stool and failure to thrive. While delayed passage of meconium beyond 48 hours is very suggestive, 50% of babies with HD do pass meconium within 48 hours of birth. Delay in treatment can lead to development of enterocolitis. Delayed passage of stools is also seen in hypothyroidism and cystic fibrosis. While delayed passage of meconium, symptoms since first month of life and abdominal distension are more common in children with organic cause, fecal impaction is more in functional group.

Digital rectal examination (DRE) reveals hard fecal matter in acquired constipation while it is empty in HD. A typical finding seen in HD is gush of fecal matter on withdrawal of fingers. DRE requires expertise, privacy and informed consent. Present guidelines do not support the routine use of DRE to diagnose functional constipation.

Flow chart 1 presents an algorithm for evaluation of constipation.

INVESTIGATIONS

Most children with functional constipation with or without fecal incontinence do not require any laboratory work-up apart from a careful history and physical examination.

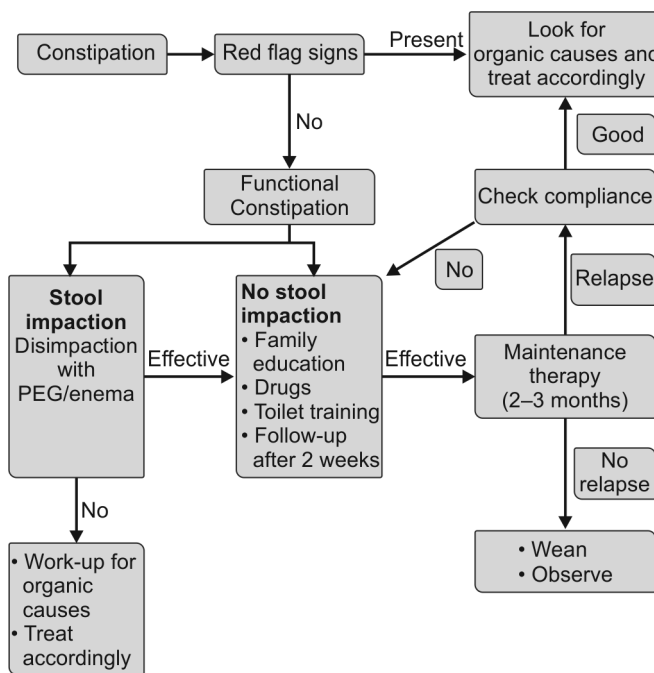

Rectal biopsy Rectal suction biopsy is the gold standard for the diagnosis of HD. It is performed around 3 cm above the anal verge, deep enough to include the submucosa. The aganglionic segment is recognized by absence of ganglion cells in submucosa and the presence of hyperplastic nerve trunks. There is absence of both ganglion cells and hypertrophied nerves in total colonic aganglionosis. Hyperganglionosis and/or ectopic ganglion cells are features of neuronal intestinal dysplasia.

Table 1 Evaluation of constipation

History	Physical examination
Stooling habits <ul style="list-style-type: none"> • Frequency, amount, diameter, and consistency of stools • Age of onset of constipation • Character of stools in toilet and underwear • Stool withholding maneuvers • Fecal incontinence 	Anthropometry: Weight, height Abdominal examination: Distension, palpable fecal mass
Any precipitating factors Change of diet, timing of/toilet training or some events such as infections, fissure, starting nursery/school, major change in family conditions	Neurological examination Tone, strength of lower limbs, deep tendon reflexes, cremasteric reflex, perianal sensation testing
Abdominal pain, vomiting and distension, poor appetite and irritability Urinary complaints Day wetting Bed wetting History of urinary tract infections	Anal size and location Position, stool present around anus or on clothes Perianal erythema Skin tags Anal fissures
Dietary habits Diet low in fiber, poor intake of fluids, high intake of dairy products Drug history: Antispasmodics, codeine containing cough preparations	Digital rectal examination Anal wink, anal tone, presence or absence of stool, consistency of stool, explosive stool on withdrawal of finger

Table 2 Red flag signs indicating organic causes of constipation

Clinical features	Diseases
Delayed passage of meconium (after 48 hours after birth), small-caliber stools, failure to thrive, tight anal sphincter, empty rectum with palpable abdominal fecal mass, gush of air and liquid stool may follow withdrawal of the examining finger	Hirschsprung disease
Abdominal distention, bilious vomiting, ileus	Pseudo-obstruction
Decreased lower extremity tone and/or strength	Spinal cord abnormalities
Absence or delay in relaxation phase of lower extremity deep tendon reflexes, absence of anal wink and cremasteric reflex or presence of pilonidal dimple or hair tuft	
Abnormal position or appearance of anus	Imperforate anus, anal stenosis, anteriorly displaced anus
History of delayed passage of meconium, fatigue, cold intolerance, bradycardia, poor growth	Hypothyroidism
Polyuria, polydipsia	Diabetes insipidus
History of delayed passage of stool, failure to thrive, fever, recurrent pneumonia	Cystic fibrosis
Chronic/recurrent diarrhea, pallor, abdominal distension	Celiac disease
Diarrhea, failure to thrive, occult blood positivity	Cow's milk protein intolerance

Flow chart 1 Algorithm for evaluation of constipation

Imaging Plain X-ray abdomen will help diagnose fecal impaction, the presence of which has implications in management. An unprepared barium enema will demonstrate a transition zone (more prominent in older children due to prolonged stool retention) separating dilated, stool-filled normally innervated ganglionic segment from an empty abnormal or aganglionic bowel segment. It is not a valid alternative to gold standard rectal biopsy.

Anorectal manometry When the above investigations are inconclusive, anorectal manometry helps in diagnosing abnormalities of defecation. Normal individuals will demonstrate relaxation of internal anal sphincter in response to rectal distension (rectoanal inhibitory reflex). This reflex gets abolished in HD and in patients with internal sphincter achalasia. In latter group, a rectal biopsy is normal despite a nonrelaxing internal anal sphincter. Other functional problems like pelvic floor dyssynergia and neurosensory rectal abnormalities can also be diagnosed using anorectal manometry.

Colonic transit study Dysfunctional (pan or segmental) colonic motility can be evaluated using radiopaque markers during colonic transit study. It is a precise tool for evaluation of colonic motor function and helps differentiate myopathy from neuropathic causes. Neuropathy is characterized by nonpropagating, disordered high amplitude contractions or an absence of the gastrocolic response while absent or weak colonic contractions is suggestive of myopathy.

MANAGEMENT

Acute constipation Identify any precipitating cause. Treat local causes like anal fissure, boil, dermatitis, etc., if any. Encourage use of high fiber diet-cereals, pulses, vegetables and fruits. Prescribe laxatives for short duration (7–10 days). Encourage toilet training if not already done.

Chronic constipation Patients with an identifiable organic cause for constipation should be appropriately treated medically or surgically. Treatment of functional constipation requires multimodality approach and includes education of parents and counseling; disimpaction and bowel cleansing; maintenance therapy; and follow-up. These measures have already been discussed in the chapter on encopresis (see section 21).

The drugs used in management of constipation are listed in **Table 3**. The first line of management of a child who presents with constipation and fecal impaction is disimpaction using polyethylene glycol (PEG) orally at a dose of 1–1.5 g/kg/day for 3–6 days. PEG is not degraded by bacteria; is not readily absorbed and thus acts as an excellent osmotic agent. If PEG is not available then disimpaction may be achieved with once a day enema for 3–6 days. Phosphate enema is better than normal saline enema. Other alternatives are glycerin suppositories in infants and bisacodyl suppositories in older children. Hospitalization may be required to treat children with severe disimpaction particularly when oral PEG is not tolerated. Such children are given nasogastric lavage and are closely monitored for abdominal distension and dyselectrolytemia during the disimpaction. Maintenance therapy (PEG 0.4 g/kg/day) is then started to maintain normal stool frequency of once or twice a day. It is important to ensure good therapeutic compliance otherwise recurrence of stool impaction can restart the constipation cycle. Maintenance therapy should be continued for at least 2 months and it should then be gradually weaned and discontinued after ensuring resolution of symptoms for at least 1 month. Parents are advised to ensure adequate water intake and daily servings of a variety of fiber-rich foods such as whole grain

Table 3 Drugs used for the treatment of constipation in children

Oral laxatives	Dose	Side effects
A. Osmotic laxatives		
Lactulose	1–2 mL/kg body weight twice/day	Bloating and abdominal distension
PEG 3350 with electrolytes	1–1.5 g/kg/day for 3–6 days (disimpaction)	Nausea, bloating, cramps and vomiting
PEG 3350 without electrolytes	Maintenance: 0.2–0.8 g/kg/day	
Milk of magnesia (magnesium hydroxide)	2 mL/kg body weight twice/day for 7 days (disimpaction) 2–5 years: 0.4–1.2 g/day, once or divided 6–11 years: 1.2–2.4 g/day, once or divided 12–18 years: 2.4–4.8 g/day, once or divided	Abdominal distension, hypermagnesemia, metallic taste. Avoid in renal failure
B. Fecal softeners		
Mineral oil	3 mL/kg body weight twice/day for 7 days (disimpaction) 1–18 years: 1–3 mL/kg/day, once or divided, max 90 mL/day	Not for infants Lipoid pneumonia if aspirated
C. Stimulant laxatives		
Bisacodyl (Oral)	3–10 years: 5 mg/day > 10 years: 5–10 mg/day	Abdominal pain, diarrhea
Bisacodyl (Suppository)	2–10 years: 5 mg once/day > 10 years: 5–10 mg once/day	Abdominal pain, skin rash, fixed drug eruption rarely
Senna	2–6 years: 2.5–5 mg once or twice/day 6–12 years: 7.5–10 mg/day	Abdominal cramps, diarrhea
Sodium picosulfate Tab 10 mg, syrups 5 mg/5 mL	1 mo–4 years: 2.5–10 mg once/day 4–18 years: 2.5–20 mg once/day	
Rectal laxatives/enemas		
Sodium docusate (lubricant)	< 6 years: 60 mL, > 6 years 120 mL	Cramps, abdominal pain
Sodium phosphate enema	1–18 years: 2.5 mL/kg, max 133 mL/dose	Hyperphosphatemia, hypernatremia, hypokalemia, hypocalcemia and dehydration
NaCl	Neonate < 1 kg: 5 mL, > 1 kg: 10 mL > 1 years: 6 mL/kg once or twice/day	
Glycerin suppository	Infants and toddlers	No side effects

breads and cereals, fruits, vegetables, and legumes in diet to ensure adequate fiber (required: age in years + 5 g/day).

Follow-up Children and their parents are instructed to maintain a record of daily bowel movements, and medication use. After regular bowel habits are established the drug dosage is gradually decreased to ensure one soft bowel movement per day. Follow-up is recommended at 1 month, 3 months, 6 months and then 3–6 monthly intervals to ensure optimal response.

Patients with *refractory or recurrent constipation* in spite of good compliance to the prescribed therapy will require detailed work-up. Metabolic tests such as serum calcium, thyroxine or thyroid-stimulating hormone, and celiac disease should be carried out. MRI of the lumbosacral spine can exclude occult spinal cord abnormalities and colonic manometry will detect occult myopathy or neuropathy. Full-thickness rectal biopsies will reliably exclude HD or neuronal intestinal dysplasia.

PROGNOSIS

Conventional treatment with adequate fiber and laxatives, toilet training is successful in approximately in 60% of cases. Adequate dose and treatment adherence is more important than which laxative is used. Good prognostic indicators are better compliance, adequate intake of roughage diet and self-confidence. Poor prognostic indicators include severe motor disability, mental retardation, school time soiling and neurogenic causes.

IN A NUTSHELL

1. Constipation is a common problem in children which can present with infrequent and or painful defecation, fecal incontinence and abdominal pain.
2. Functional constipation is most common cause accounting for 90–95% of cases.
3. Most children with functional constipation with or without fecal incontinence do not require any laboratory work-up apart from a careful history and physical examination. Presence of red flags increases possibility of underlying organic cause.
4. The most common organic cause in young children is Hirschsprung disease accounting for 6% of all patients.
5. Treatment of functional constipation requires multimodality approach and includes education of parents and counseling; disimpaction and bowel cleansing; maintenance therapy; and follow-up.
6. The first line of management of a child who presents with constipation and fecal impaction is disimpaction using polyethylene glycol (PEG) orally at a dose of 1–1.5 g/kg/day for 3–6 days.
7. Maintenance therapy should be continued for at least 2 months and it should then be gradually weaned and discontinued after ensuring resolution of symptoms for at least 1 month.

Chapter 35.11

Hirschsprung Disease

Ketan Parikh

Hirschsprung disease (HD) is characterized by a congenital aganglionosis of a variable length of the distal colon extending proximally from the anorectal junction. The incidence ranges from 1:4,000 to 1:7,000 newborns in various series. The disease is usually sporadic but occasionally runs in families. Male:female ratio is 4:1 however in females the length of the aganglionic bowel is often longer. HD usually presents with chronic constipation.

PATHOGENESIS

Normal peristaltic activity involves a wave of relaxation preceding a wave of contraction. Parasympathetic innervation is essential for this wave of relaxation. In HD, the parasympathetic ganglia are absent from the Meissner's and Auerbach's plexuses of the affected bowel. The aganglionic bowel is normal in caliber but because of the absence of the peristaltic activity, the wave of relaxation is absent thus leading to a functional obstruction. The chronic obstruction leads to massive dilatation and hypertrophy of the normally ganglionated proximal bowel. The junctional portion of the bowel often shows a section of hypoganglionosis with partial function. The mucosa in the proximal hypertrophied portion of the bowel may show ulceration and hyperplasia due to chronic inflammation due to stagnation.

CLASSIFICATION

Depending on the length of the segment of aganglionosis, the disease is categorized as *short segment* (aganglionosis restricted to either the rectum or the rectosigmoid); *long segment* (extending more proximally to colon); *total colon* (entire colon); *very long segment* (a portion of the small bowel is also aganglionic); *total bowel* the entire bowel (small and large) is aganglionic—almost incompatible with normal life) and *ultrashort segment* (aganglionosis restricted only to the terminal portion of the rectum).

CLINICAL FEATURES

At birth, there is failure to pass meconium for more than 48 hours after birth and gradual onset of intestinal obstruction. Even if the baby passes meconium with some assistance, he again may get obstructed. There may be a persistent passage of meconium even until 1 week of life.

In case the disease does not manifest at birth, it presents later with constipation dating back to early infancy. Intestinal obstruction may manifest at any age which may be relieved by enemas. Rarely, attacks of foul smelling diarrhea interspersed with constipation may confuse the picture. In chronic cases—child fails to thrive and is malnourished. Abdominal distension is marked and the transverse colon is often visible. On rectal examination—the rectum is felt to be empty, and on withdrawal of the examining finger, there is an explosive passage of flatus and feces.

DIAGNOSIS

Most of the diagnostic techniques for HD have been described in the previous chapter on constipation. A plain X-ray of the abdomen may show features of intestinal obstruction—large dilated colon loops. It may also show absence of rectal gas shadow. Barium enema reveals a narrow aganglionic segment

and a cone-shaped colon at the junction of the ganglionic and aganglionic segments (**Figs 1 and 2**). Anorectal manometry may strongly suggest the diagnosis of HD. The final confirmation is only with a full thickness biopsy of the rectal wall which will show absence of ganglion cells.

TREATMENT

Conservative treatment involving repeated enemas/suppositories may help in overcoming an acute attack of intestinal obstruction and may help to postpone the surgery. However, many infants may not respond at all to conservative treatment and may need an emergency surgery. In such a case, an emergency colostomy may be the only option to save the child.

The principle of the surgery is the removal of the aganglionic segment of colon and ensuring that normal ganglionic bowel is anastomosed to the terminal rectum as close as possible to the anal canal. Traditionally this surgery is done in stages but in recent years, single stage surgery is being done with variable success rates.

Various commonly performed surgeries include the modified Duhamel's procedure, Swenson's procedure and Soave's procedure. Either of these may be performed by regular laparotomy or by laparoscopic methods.

Source: Dr Praveen Kumar, New Delhi.

Figure 2 Barium enema of Hirschsprung disease showing the cone

IN A NUTSHELL

1. Hirschsprung disease (HD) should be suspected in any apparently normal newborn who fails to pass meconium in the first 24 hours.
2. Hirschsprung disease should be suspected in any child who has repeated attacks of enterocolitis (profuse explosive diarrhea) interspersed with constipation.
3. Most patients with HD do not have soiling/encopresis.
4. A palpable fecaloma—low in the rectum is not likely to be due to HD.
5. Rectal biopsy is diagnostic of HD.

Chapter 35.12

Chronic Abdominal Pain

B Bhaskar Raju, Sumathi Bavanandam

Abdominal pain is a common complaint in pediatric practice, with at least 15% of all outpatients suffering from it. *Recurrent abdominal pain* (RAP) which troubles the child periodically with pain-free intervals in between, is so common, that the term RAP was used as a specific diagnosis for several decades, to refer to a condition wherein, pain occurs at frequent intervals with no organic cause made out on examination or investigation. Today, the same is referred to as *chronic abdominal pain* (CAP). Functional abdominal pain, which is the most common form of CAP seen in clinical pediatric practice, has been discussed here. There are many organic and nonorganic causes of abdominal pain in children within and outside the gastrointestinal tract (GIT); they will be touched upon, but not discussed in detail, since that would be beyond the scope of this chapter.

CHRONIC FUNCTIONAL ABDOMINAL PAIN

Even though functional abdominal pain is a benign disorder, it is something to be taken seriously since it troubles the child and the whole family. It has to be clearly differentiated from malingering, wherein the child feigns pain for some reward like avoiding school or homework, or just for the sake of sympathy. Functional abdominal pain is true pain that is actually felt by the child. Chronic functional abdominal pain (CFAP) may also present as functional dyspepsia; irritable bowel syndrome; abdominal migraine; or a combination of the above.

Chronic functional abdominal pain is a specific diagnosis to be made after ruling out all anatomic, infectious, inflammatory and metabolic causes of abdominal pain. Presence of red flag signs and symptoms should warn the physician to make every effort to rule out organic causes of CFAP. The final diagnosis of CFAP will always depend upon a good clinical history, and a thorough physical examination of the child, besides evaluation of precipitating and reinforcing factors in the family and immediate environment of the child.

DEFINITIONS

Any abdominal pain that exceeds 8 weeks in duration is said to be chronic. Previous definitions of RAP insisted on presence of pain-free intervals and number of bouts of pain are obsolete. Apley and Naish, who were the first to scientifically study children with abdominal pain syndrome as early as 1958, defined RAP as three or more episodes of abdominal pain that occurred over 3 months, that were severe enough to interfere with the child's daily activities. Rome III criteria, which clarifies and defines all functional disorders of GI system in adults, children and infants, has two pediatric categories based on age. It defines CAP as any pain recurrent or continuous, lasting beyond 8 weeks.

PREVALENCE

Functional gastrointestinal disorders (FGID) account for more than 50% of consults in pediatric gastroenterology practice and a significant proportion is CFAP. CFAP is diagnosed in 2–4% of all cases in general pediatric practice in the West. Epidemiological studies in Europe and America have shown prevalence rates of RAP/CAP varying between 0.5% and 19% among school going children. Apley and Naish found that the incidence of detectable pathology in RAP was less than 8%. Among growing children

10–15% experience RAP over 8 weeks, sometime in their life, with the highest prevalence in middle school girls. However, many Indian and Pakistani studies which screened children for CAP in schools that cater to poorer socioeconomic strata, found a disproportionately high incidence (84%) of minor organic pathology in their cohort of CAP children, giardiasis being the most common. Given the ubiquitous nature of giardiasis in poorer societies, this finding is understandable. Studies from India and Sri Lanka that looked at CAP in urban settings with more hygienic environments reflect Western numbers; 74–76% of CAP being nonorganic. In Malaysia, the prevalence of CAP in urban and rural population-based cohorts is 9.6% and 11%, respectively, most of it being functional. Abdominal migraine affects 1–4% of school going children in the West, with girls being affected more than boys; mean age of onset is 7 years, peaking at 10–12 years.

PATHOPHYSIOLOGY

Functional CAP is essentially a disorder of gut-brain neural cross talk. Gut has more neurons and complicated neural interconnections than even the brain in higher primates. The *enteric nervous system* (ENS) as it is called, consists of two major collections of neurons called (1) Auerbach's plexus which is essentially a myenteric system controlling GI motility and (2) the Meissner's plexus which is essentially a submucosal system that controls secretions and has sensory functions as well. The interstitial cells of Cajal which are interspersed between the nerve endings and smooth muscles of GIT, act as pace makers, regulating propagation of intestinal contractions. ENS is responsible for the motor, sensory and vascular responses of the entire GIT to intrinsic and extrinsic stimuli and it extensively interacts with the central nervous system (CNS) through the vagus nerve. The ENS and CNS profoundly influence each other and abnormalities in ENS and its response to the CNS inputs are the basis for the pain felt in CFAP.

Recent research on the pathophysiology of functional bowel disorders focuses on two disordered physiological functions in children with CFAP—(a) heightened response to visceral pain (visceral hyperalgesia); and (b) disturbed bowel motility.

Visceral hyperalgesia This is otherwise known as augmented visceral perception or visceral hypersensitivity. This refers to the capacity of children with CFAP to feel events in the gut that are otherwise usually imperceptible to normal children. Signals from Meissner's plexus are generally filtered at the hypothalamus (hypothalamic gate) and very few signals make their way for perception by the cortex. This explains why most intestinal activity is not felt. Children with CFAP however, feel physiological events like peristalsis, postprandial and gaseous distension of gut, as pain, thanks to augmented visceral perception. Many studies have documented enhanced awareness and pain in response to balloon distension of the rectum in these children. Almost a third of them also have autonomic disturbances with pain episodes, like dizziness, headaches, vomiting, pallor, temperature intolerance, also indicating the role of the nervous system in CFAP. Mucosal inflammatory processes secondary to infections, allergy, and primary inflammatory diseases may also cause sensitization of afferent nerves and visceral hyperalgesia, resulting in augmented visceral pain perception. This explains the often elicited history that the CAP started with a bout of diarrhea and vomiting.

Altered intestinal motility Besides augmented visceral perception, children with CFAP have significantly increased amplitude of both peristaltic and nonperistaltic contractions of intestine. Levine's famous hypothesis tries to understand this phenomenon of increased cortical stimulation of gut musculature through his conceptual model of CFAP (**Fig. 1**). This model suggests various external and intrinsic stimuli can trigger inappropriate contractions

of the bowel, felt as pain by the child. The normal function of the CNS is to integrate all interoceptive inputs from gut and elsewhere in the body, and accordingly send back efferent neuronal signals to GIT which trigger myoactivity in the intestines. Aberrations in this integration and response from the CNS result in inappropriate and enhanced bowel contractions felt as pain by the child.

Levine's Hypothesis

Levine suggests CFAP is triggered and induced by several intrinsic and extrinsic inputs inducing pain in a susceptible child who has heightened sensitivity to visceral sensations and increased bowel activity secondary to CNS inputs (**Fig. 2**).

Lifestyle and habits Regular eating habits, an active lifestyle including exercise and regular bowel habits improve CFAP symptoms, lack of them predispose to CFAP.

Temperament and learned responses Learned responses refer to children who respond poorly to discomfort and pain with exaggerated responses because of being petted and pampered. They do not take disappointment well. If secondary gain is involved, their expression of discomfort worsens. For example, allowing children to skip school on account of pain makes pain episodes worse and more frequent.

Somatic predisposition Chronic functional abdominal pain tends to run in families (Pain families). This may have a genetic predisposition, but it is more likely that there is modeling involved. Children mimic their parents' complaints and tendency to complain and grumble.

Figure 1 Schematic representation of pathophysiology of functional abdominal pain (FAP)

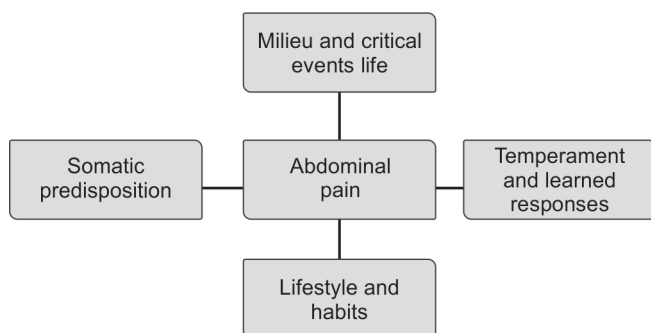

Figure 2 Environmental factors and cortical stimulation of increased gut activity

Milieu and critical events These refer to several events in a child's life, besides examinations, that can be stress triggers for pain. Loss of a friend, relocation to a new home and family discord can all precipitate pain episodes.

CLINICAL PRESENTATION

In the 80s, all RAPs were classified as organic (10%) or psychogenic (90%). Later psychogenic pain was split into dysfunctional abdominal pain (95%), and RAP due to psychiatric problems (5%). Dysfunctional abdominal pain is presently called CFAP. Given the complexity of presentation of FGID, attempts were made to streamline, define and clarify these disorders. The third committee on functional disorders of GIT (adults, children and infants) met in Rome and published the scholarly treatise on FGID, called Rome III criteria for FGIDs in 2006. As per Rome III criteria, all childhood functional abdominal pain disorders are one of four types:

1. **Functional dyspepsia:** This is characterized by rapid gastric emptying associated with slow bowel transit. Children with this disorder have poor appetite, dyspepsia and postprandial bloating as predominant symptoms, instead of pain.
2. **Irritable bowel syndrome (IBS):** Symptoms of IBS include altered stool frequency (four or more stools/day or two or less stools/week), abnormal stool form (lumpy/hard or loose/watery stool), abnormal stool passage (straining, urgency, or feeling of incomplete evacuation), passage of mucus and bloating or feeling of abdominal distension. Abdominal pain may or may not be a part of the syndrome.
3. **Abdominal migraine:** Defined as severe paroxysmal periumbilical pain, often intense, lasting 1 hour or more, interspersed with pain-free intervals, lasting weeks to months. Investigations fail to reveal any evidence of inflammatory, anatomic, metabolic, or neoplastic process attributable for subject's symptoms. Pain interferes with normal activities and pain episodes are associated with two or more of the following symptoms like anorexia, nausea, vomiting, headache, photophobia, or pallor.
4. **Childhood functional abdominal pain:** Characterized by episodic or continuous abdominal pain (mild to moderate) with insufficient criteria for other FGIDs, in the absence of an inflammatory, anatomic, metabolic, or neoplastic process that explains the subject's symptoms.

(Criteria to be fulfilled at least once per week for at least 2 months before diagnosis).

FUNCTIONAL ABDOMINAL PAIN SYNDROME (FAPS)

The term syndrome is used for functional abdominal pain, if at least 25% of pain episodes include, interference with daily activities, sleep disturbances, other somatic symptoms like headache and limb pains (criteria to be fulfilled at least once per week for at least 2 months before diagnosis).

Typical pain pattern in functional pain is characterized by paroxysmal nature of pain with variable severity; clustering of pain; gradual onset; usually periumbilical, occasionally epigastric location; poor relationship to food, defecation and inability to clearly describe nature or localize the pain. It may be associated with other symptoms like pallor/nausea/fatigue/anxiety in about 10% of the cases. It should be differentiated from the typical pain pattern in organic pain which is well defined and clearly localized, away from the umbilicus, and may be radiating. Burning, stabbing pain; pain awakening the child at night; pain with fever; pain with weight loss; tenderness/organomegaly; blood in stools (occult or obvious); altered bowel movements; anemia, urinary symptoms, increased erythrocyte sedimentation rate/C-reactive protein

(ESR/CRP) and associated arthralgia/rash/purpura are the red flag signs that should immediately warn the physician that he could be dealing with an organic pathology, requiring diligent investigations to identify it.

EVALUATION

History, clinical examination and the presence or absence of red flag signs/alarm symptoms, help to differentiate between organic and nonorganic causes of pain in clinical practice. Many studies especially in India, have picked up conditions like constipation, gastroesophageal reflux disease (GERD) esophagitis, *Helicobacter pylori* (*H. pylori*) gastritis, lactase deficiency, and rarely inflammatory bowel disease (IBD) and celiac disease, in what was clinically diagnosed to be functional abdominal pain. As a general rule, if the pattern of abdominal pain appears functional, with a completely normal history and physical examination without occult blood or parasites in stool and bowel movements are normal, a physician is justified in diagnosing CFAP without extensive investigations. But, he must follow-up the child closely, however, and whenever red flag signs appear or pain relief is not observed with time, he must order investigations to rule out organic causes.

Besides a detailed history and physical examination, all cases of suspected CFAP require evaluation of the child's interpersonal relationship with the rest of family especially parents, siblings, grand parents and friends; child's immediate emotional environment in school and home; child's personality; child's response to discomfort and pain; sociability and school performance/problems.

INVESTIGATIONS

Majority of cases of CFAP can be picked up on clinical examination and most do not require investigations other than stool microscopy and occult blood. Where pain in CFAP has been long-standing, and reassurance does not result in relief of pain, investigations are order of preference are listed in **Box 1**.

Before a child is finally labeled CFAP, it is wise to keep in mind some conditions that cause RAP, but may be easily missed by both clinical examination as well as by investigations. These include GERD (may be missed if not biopsied), *H. pylori* gastritis (requires biopsy), constipation, chronic appendicitis/appendicular colic, giardiasis/pinworms, leukemia (iliac bone pains), hernias (linea alba) and spinal lesions.

MANAGEMENT

Principles of management are summarized in **Box 2**. The goal of therapy does not include complete relief of pain which may not be possible in short-term. Reassurance of the parents and child that nothing is wrong with him/her is the cornerstone of therapy in CFAP. Most children with CFAP tolerate pain better, once reassured there is nothing seriously wrong and the parental anxiety about pain disappears. The aim should be to have normal school attendance and scholastic and sports activities to the child's potential. Counseling by the pediatrician usually achieves all these. Some severe cases that do not respond to reassurance and counseling may need additional modalities like:

- Cognitive behavioral therapy
- Psycho education
- Relaxation based therapy.

Dietary management includes reduction in sugary foods, sodas and irregular eating habits. Increase in fiber intake also helps. Food allergies are increasing in incidence and a good dietary history might unravel food allergies. If found, avoidance will help. Lactose intolerance, which is an important cause of RAP in Caucasian population, is, however, rare in India beyond infancy.

BOX 1 Investigations for chronic pain abdomen

Level I investigations

- Complete hemogram
- Serum amylase/lipase/liver and renal function tests
- Stool and urine analysis
- Screening for tuberculosis
- Ultrasonography (USG) of abdomen

In the absence of red flag signs, when the above set of investigations are normal, one can label the child as having CFAP. If the above investigations fail to pick up any pathology and the child presents with one or more red flag signs, additional investigations may be needed (*Level II investigations*). Pain with altered bowel movements, occult blood positive in stool, anemia, ↑ESR/CRP, fever, rash and recurrent aphthous ulcers, merit direct visualization of the bowel, both upper and lower.

Level II investigations

- Contrast studies of upper and lower GIT
 - Upper and lower GI endoscopies, including appropriate biopsies
- Inability to identify a cause with level II investigations, with persistence of pain occurred in less than 1% of cases in our series. They will need third level investigations to identify rarer causes of recurrent abdominal pain.

Level III investigations

- EEG to rule out abdominal epilepsy and cyclical vomiting disorder
- Screening for porphyrias/lead poisoning/collagen vascular disorders/lactose intolerance/food allergies/motility disorders.

Abbreviations: CFAP, chronic functional abdominal pain; ESR, erythrocyte sedimentation rate; CRP, C-reactive protein; EEG, electroencephalogram.

BOX 2 Principles of management of chronic abdominal pain

- Arriving at a positive diagnosis
- A detailed explanation of the pathophysiology and the cause of pain to parents and child
- Establishing goals of therapy and explaining that complete relief of pain is not one of them
- Identification and modification of triggers and physical or psychological stress
- Diet modification
- Drug therapy in selected cases
- Active psychological support
- Avoidance of hospitalization
- Avoidance of psychiatric consults, unless strong evidence for an underlying psychiatric disorder exists.

Medications

Drugs are uniformly useless in CFAP except in selected situations. Functional dyspepsia may respond to proton pump inhibitors (PPIs) and prokinetics and so does documented acid peptic disease including GERD. Antispasmodics are best avoided in CFAP, except in IBS with a significant pain component. They precipitate gastroesophageal reflux and constipation. Peppermint oil has been found useful in IBS and some cases of CFAP. Stool softeners benefit children with constipation. Abdominal migraine if suspected, would do well with pizotifen. Recently, many trials have looked at probiotics like *Lactobacillus* GG, *Bifidobacterium*, VSL#3, and have reported mixed results. Antimotility agents are best avoided, except in severe diarrheal forms of IBS. In endemic areas, empirical metronidazole therapy for giardiasis might help. Routine deworming has no role in CFAP therapy. Treatment of *H. pylori*, even when identified in biopsy has had only equivocal effect. Typical CFAP does not need antipsychotic medication. Psychiatric consult often scares the parents and child and worsens the pain and may be avoided, unless an underlying psychiatric disease is suspected. A multidisciplinary team including a psychiatrist will

be needed in the following situations: conversion reaction; low self-esteem; anxiety, depression; maladaptive family; modeling/imitating family behavior; or poor response to conservative therapy.

PROGNOSIS

About 70% of CFAP children have complete relief of pain without any medication, with just a positive diagnosis and reassurance that there is nothing seriously wrong with them. Many do get recurrences, but they too remit well. About a third of them grow into adulthood with abdominal pains. An equal number develop new symptoms like headaches, back pains, etc. CFAP children, however, handle pains much better as they grow into adulthood.

CHRONIC ABDOMINAL PAIN: ORGANIC CAUSES

It is beyond the scope of this chapter to deal with all pathology that could present with CAP, but some guidelines are given as to what diseases to screen for depending on presentation of the pain.

Child presenting with isolated periumbilical paroxysmal pain (IPUPP) Screen for renal/biliary/pancreatic colic, malrotation, abdominal epilepsy, intussusception, vasculitis (Henoch-Schönlein purpura), porphyrias, less than 5% of children with IPUPP actually have an organic basis. Others are functional in origin.

Child presenting with CAP and significant dyspepsia GERD, peptic ulcer disease, *H. pylori* infection, giardiasis, pancreatitis and motility disorders.

Child presenting with CAP and altered bowel movements Simple constipation, IBDs, abdominal tuberculosis, immunodeficiency syndromes, intestinal lymphomas, eosinophilic enteritis, postoperative adhesions and congenital band obstructions.

Almost one-third of patients with CAP and significant altered bowel habits will have an organic basis for the pain, the rest will be functional.

IN A NUTSHELL

1. The term RAP is now replaced by CAP.
2. Chronic functional abdominal pain is a specific diagnosis, made after ruling out anatomic, infectious, inflammatory, or metabolic causes of abdominal pain.
3. Chronic functional abdominal pain includes functional dyspepsia, irritable bowel syndrome, abdominal migraine, and FAPS.
4. A clinical diagnosis of CFAP can be made in children between 4 years to 18 years of age when alarm symptoms/signs are absent and physical examination is normal, provided stool microscopy and occult blood test are negative.
5. Alarm symptoms requiring investigations include involuntary weight loss, linear growth deceleration, anemia due to GIT blood loss, significant vomiting, chronic diarrhea, persistent right upper or lower quadrant pain, unexplained fever and any family history of inflammatory bowel disease.
6. Alarm signs that require investigations include localized right upper or lower quadrant tenderness, localized fullness, mass, organomegaly, costovertebral angle tenderness, spine tenderness, and perianal abnormalities like fistula or abscess.
7. Investigations are indicated if pain significantly decreases quality of life and interferes with routine activities, even if alarm signs and symptoms are absent.
8. Psychological factors should be addressed during diagnostic evaluation and management and if found contributing to pain, should ideally be handled by counseling by pediatrician.
9. Time-limited use of medications, such as acid-reduction therapy, antispasmodic agents, smooth muscle relaxants, low doses of psychotropic agents, nonstimulant laxatives or antidiarrheals may be appropriate in selected cases to decrease symptom frequency or severity.
10. The role of antidepressants (tricyclics, selective serotonin reuptake inhibitors) in the treatment of FGIDs associated with abdominal pain needs to be assessed.

Chapter 35.13

Acid Peptic Disease

R Bhanu Vikraman Pillai

Acid peptic disease is one of the important treatable causes of abdominal pain. The term encompasses esophagitis, gastritis, peptic ulcer disease and duodenitis. It is important to identify these causes and treat them appropriately for the resolution of symptoms as well as prevention of certain conditions with lifelong implications. Acid peptic diseases are relatively common causes of abdominal pain in children, but are less common than chronic constipation or irritable bowel syndrome. Peptic ulcer disease, either primary or secondary, is an important but uncommon cause of abdominal pain in children compared to adults. Since gastroesophageal reflux disease (GERD) as well as *Helicobacter pylori* (*H. pylori*) infection is described in detail elsewhere, we will restrict our discussion to the rest of the spectrum.

PATHOPHYSIOLOGY

It is important to recall the different types of cells in the stomach and their functions. In the body and fundus of the stomach, they include the chief cells producing pepsinogen, parietal cells producing acid and intrinsic factor, enterochromaffin-like cells producing histamine, enterochromaffin cells secreting serotonin and D-cells secreting somatostatin. The antrum contains mucus glands, gastrin secreting G-cells, some D-cells and enterochromaffin cells.

The pathophysiology of peptic disease involves the imbalance between the aggressive and protective factors of the gastric mucosa. Gastric acid and pepsin are the major aggressive factors. Acid secretion is an active process in the parietal cells by the enzyme H^+/K^+ -ATPase, which is the proton pump. In term neonates, acidification of the gastric contents occurs soon after birth. The acid production gradually increases and reaches adult levels by 24 weeks. Gastric acid production is increased in duodenal ulcers but not in gastric ulcers. The bicarbonate-mucus barrier protects the mucosa from the acid-pepsin attack. The gastric epithelial cells secrete mucus continuously, and most importantly it is stimulated by the prostaglandins. The mucus barrier forms the *unstirred layer* and lies directly over the epithelial cell layer and protects the mucosa from the harmful effects of acid and pepsin. The mucin glycoprotein at the luminal side of the unstirred layer is broken down by pepsin, but is replaced by the continuous production of mucus by the epithelial cells. However, when there is a disruption of mucus production by infections, ischemia or noxious agents such as nonsteroidal anti-inflammatory drugs (NSAIDs), it predisposes the mucosa to attack by the acid and pepsin that could result in peptic ulcer disease.

ETIOLOGY

There are several causes for gastritis in children. By strict definition, gastritis is a histologic diagnosis and should have inflammatory cells; but in gastropathy, there is mucosal injury without significant inflammation. However, the terms gastritis and gastropathy are used together since the clinical symptoms are similar. The causes of gastritis or gastropathy in children are listed in **Box 1**; few important ones are discussed here.

Infection *H. pylori* is well known to cause of gastritis. It can cause nodular gastritis, erosions, as well as peptic ulcer disease. World Health Organization (WHO) has classified *H. pylori* as a group 1 carcinogen as it is associated with adenocarcinoma as well as lymphoma arising from mucosa-associated lymphoid tissue

BOX 1 Causes of gastritis in children

- Stress gastritis
- *Helicobacter pylori* gastritis
- Nonsteroidal anti-inflammatory drugs-induced gastritis
- Other drug-induced gastritis including iron
- Crohn's disease
- Eosinophilic gastritis
- Allergic gastritis
- Cytomegalovirus gastritis
- Corrosive-induced gastritis
- Graft versus host disease
- Gastritis associated with chronic granulomatous disease
- Bile gastropathy
- Gastritis associated with autoimmune disorders
- Pernicious anemia
- Radiation-induced gastritis
- Collagenous gastritis
- Gastric lymphoma (mucosa-associated lymphoid tissue lymphoma).

(MALToma) of the stomach. These are fortunately very rare in children. In addition to *H. pylori*, *H. heilmannii* infection has also been implicated in gastritis. *H. pylori* infection is discussed in detail elsewhere.

Drugs Nonsteroidal anti-inflammatory drugs are very frequently prescribed medications in rheumatologic conditions and can result in a spectrum of mucosal damage ranging from microscopic changes to frank ulceration and bleeding or even perforation. Cyclooxygenase (COX)-catalyzes conversion of arachidonic acid to prostaglandins. The beneficial and harmful effects of NSAIDs are due to their ability to inhibit this reaction. The most common site of NSAID-induced damage is the stomach, but it certainly can damage the small bowel, colon as well as esophagus. The prostaglandins produced by COX-1 pathway are responsible for hemostasis and mucosal integrity; while those produced in the COX-2 pathway are responsible for pain, fever and inflammation. The nonselective NSAIDs such as aspirin, ibuprofen, indomethacin, diclofenac, mefenamic acid and meloxicam inhibit both pathways, and are more likely to cause GI side effects. The COX-2 inhibitors such as celecoxib or rofecoxib are less likely to cause GI side effects, but are not totally safe. As NSAIDs are protein-bound, hypoalbuminemia increases the serum levels of free drugs which increase the risk for toxicity.

Allergy Food allergies can cause eosinophilic gastritis as well as eosinophilic esophagitis. It can be isolated or be part of eosinophilic gastroenteritis. In children, the proteins of cow's milk, soy, wheat and egg are the most commonly encountered allergens. Peripheral eosinophilia may or may not be seen. Ménétrier's disease is a rare disorder with giant, hypertrophied gastric folds with excessive mucus production and protein-losing gastropathy. This could be associated with cytomegalovirus (CMV) infection. In children, it is considered benign and self-resolving, whereas in adults it can be an acquired premalignant condition.

Graft versus host disease (GVHD) Acute GVHD which occurs between 21 days and 100 days after transplantation may present with nausea, vomiting, diarrhea and abdominal pain and GI bleed. GVHD usually occurs after allogeneic bone marrow transplantation, but rarely after solid organ transplant also. They have characteristic histologic features. Chronic GVHD rarely involves the stomach. Pernicious anemia is associated with body-predominant atrophic gastritis, and results in loss of secretory function of acid, pepsinogen as well as intrinsic factor causing achlorhydria and anemia from vitamin B₁₂ deficiency. These patients have antibodies against parietal cell components.

Crohn's disease may cause gastritis resulting in abdominal pain, hematemesis, melena and delayed gastric emptying. Up to 30% patients with Crohn's disease have histologic evidence of gastritis with granulomas. Granulomatous gastritis can also occur in chronic granulomatous disease of childhood.

Zollinger Ellison (ZE) syndrome is caused by gastrinomas and has fasting hypergastrinemia, usually greater than 125 pg/mL, resulting in hyperchlorhydria. ZE syndrome can be sporadic, or associated with multiple endocrine neoplasia type 1 (MEN1). Gastrinomas can occur in pancreas as well as stomach, duodenum, liver and kidney. In addition to refractory peptic ulcerations, ulcerations may occur in unusual locations such as jejunum. They present with abdominal pain, diarrhea, heartburn, weight loss as well as GI bleeding. ZE syndrome associated with MEN1 presents with nephrolithiasis in addition to abdominal pain, heartburn and GI bleeding. Pseudo-ZE syndrome or G-cell hyperplasia also causes hypergastrinemia, hyperchlorhydria as well as peptic ulcerations, but there is no response to gastrin stimulation, unlike in ZE syndrome.

CLINICAL PRESENTATION

Epigastric pain is an important symptom of acid peptic disease in children. It may be associated with vomiting and nocturnal awakening. The temporal relationship with food is noted only in 50% of children with peptic ulcer disease. Some children may present with upper gastrointestinal (GI) bleed in the form of hematemesis or melena, while some may have associated heartburn, weight loss or iron deficiency anemia. Occult GI bleeding in a child with abdominal pain and vomiting needs to be investigated for possible peptic ulcer disease or other etiologies such as inflammatory bowel disease or eosinophilic disorders.

PRIMARY VERSUS SECONDARY PEPTIC ULCER DISEASE

Peptic ulcer disease can be classified as primary or secondary, based on whether or not there is an underlying systemic disease. Most primary peptic ulcers develop between 8 years and 17 years of age, whereas the secondary peptic ulcers can develop at any age. Even though *H. pylori* associated peptic ulcer is rare in children, it is the most common cause of primary peptic ulcer disease. Less commonly, ulcer can develop even if *H. pylori* is negative. Up to 29% of duodenal ulcers can be *H. pylori* negative. Hence, when *H. pylori* is ruled out by more than one test and there is no history of recent NSAIDs or antibiotics, ZE syndrome and G-cell hyperplasia, which can also cause primary peptic ulcer disease, should be excluded.

DIAGNOSIS

The definitive diagnosis of gastritis and peptic ulcer disease is by upper GI endoscopy (**Fig. 1**) and biopsy. The diagnosis of *H. pylori* is discussed elsewhere. Barium studies are not relevant currently given the high rates of false-negatives as well as false-positives. However, barium contrast studies are useful in identifying complications such as gastric outlet obstruction. If there is suspicion of ZE syndrome due to persistent peptic ulcers, further investigations like computed tomography, magnetic resonance imaging as well as radionuclide octreotide scanning and selective arterial secretin testing to locate the gastrinoma may be necessary.

Figure 1 Duodenal ulcer

TREATMENT

The treatment of *H. pylori* is discussed elsewhere. Acid suppression is the mainstay in the treatment of gastritis as well as peptic ulcer disease. In addition to acid suppression, treatment specific to the etiology such as avoiding NSAIDs when possible is essential. Ulcerations from Crohn's disease require immune modulator therapy. Eosinophilic gastritis would need avoidance of the allergic foods and at times corticosteroid therapy. Proton pump inhibitors (PPI) are very effective in acid suppression and are now the preferred drugs for acid suppression. There are sufficient data on the safety and efficacy of PPIs in children, even though most of the studies are done in patients with GERD. H_2 -receptor antagonists such as ranitidine and famotidine may be used, but are less effective than PPIs and many patients develop tolerance or tachyphylaxis. Sucralfate may be used for short term, and in acid pH, the molecule dissociates and binds to damaged tissue. It contains aluminum and should be used with caution in renal failure.

Diet should be modified so as to avoid carbonated and caffeinated drinks that increase acid secretion. Every effort should be made to discourage and stop cigarette smoking which predisposes to ulcer formation and complications, probably by inhibition of prostaglandin synthesis.

Bleeding from the ulcer can usually be controlled endoscopically. However, at times one may need help from the interventional radiologist for hemostasis by coiling or embolization. Surgical treatment may be necessary for complications such as perforation, refractory bleeding and gastric outlet obstruction.

IN A NUTSHELL

1. Acid peptic diseases are relatively common causes of abdominal pain in children, but less common than chronic constipation or irritable bowel syndrome. Peptic ulcer disease, either primary or secondary is important but uncommon cause of abdominal pain in children compared to adults.
2. The pathophysiology of peptic disease involves the imbalance of the gastric mucosal aggressive and protective factors.
3. The definitive diagnosis of gastritis as well as peptic ulcer disease is by upper GI endoscopy and biopsies.
4. Both the primary and secondary causes of gastritis require treatment of the underlying pathology as well as acid suppressive therapy.
5. Acid suppressive therapy is best achieved by PPI and is effective and safe in children.

Chapter 35.14

Pancreatitis

A Riyaz, Geeta M Govindaraj

ACUTE PANCREATITIS

Pancreatitis is inflammation of the parenchyma of the pancreas caused by the destructive effects of pancreatic enzymes, resulting in acinar cell injury. Traditionally considered a very rare disease in children, their numbers have increased over the past decade all over the world. This is possibly due to greater awareness of the disease among pediatricians. Ninety percent of children have acute pancreatitis and 10% chronic pancreatitis. However, pancreatitis being a mild disease in children unlike adults, the diagnosis may be easily missed, if the pediatrician is not aware of the problem.

CLASSIFICATION

Acute pancreatitis is a reversible process which does not cause any lasting effects on the pancreatic parenchyma or function. In contrast, *chronic pancreatitis* is a prolonged and frequently lifelong disorder secondary to fibrosis within the pancreas.

The *Atlanta classification* categorizes acute pancreatitis into mild and severe types. Mild acute pancreatitis has minimal organ dysfunction and has a self-limited course with an uneventful recovery. Severe acute pancreatitis consists of organ failure and/or local complications such as pseudocysts, necrotizing pancreatitis or abscess.

ETIOLOGY

The major causes of acute pancreatitis in children are infections, trauma, drugs and systemic diseases. This is in contrast to adults in whom it is caused mainly by gallstones and alcohol abuse, and to some extent by hypercalcemia and hypertriglyceridemia.

Infections

Viral infections that cause pancreatitis include mumps, rubella, varicella, measles, influenza, infectious mononucleosis, etc. Serum amylase and lipase may be elevated in about 70% children with mumps, but pancreatitis rarely occurs. Viral hepatitis, especially hepatitis A and B may also cause pancreatitis. Human immunodeficiency virus (HIV) infection causes pancreatitis by several mechanisms. The virus may directly affect the gland. Opportunistic infections caused by cytomegalovirus, *Mycobacterium avium-intracellulare*, *Mycobacterium tuberculosis*, *Cryptococcus neoformans* (*Torula histolytica*), *Cryptosporidium parvum*, *Toxoplasma gondii*, *Histoplasma capsulatum*, and *Candida* species may also cause pancreatitis. Pancreatic neoplasms like Kaposi's sarcoma and lymphoma seen in about 5% of patients with acquired immunodeficiency syndrome (AIDS) may also be responsible. Hydroxyurea as well as several antiretroviral drugs like stavudine and didanosine are notorious to cause pancreatitis. Hence, it is important to rule out HIV/AIDS in children with obscure pancreatitis.

Some bacteria like *Shigella*, *Campylobacter*, *Enterohemorrhagic Escherichia coli* 0157, *Legionella*, *Leptospira*, *Mycobacterium* and *Brucella* cause acute pancreatitis by releasing various toxins. There are several reports of severe pancreatitis complicating enteric fever. In developing countries like India, helminth infections caused by *Ascaris lumbricoides* (roundworms) may cause severe pancreatitis by blocking the main pancreatic duct and obstructing drainage of pancreatic secretions. It is difficult to diagnose and treat this condition. *Aspergillus fumigatus* and *Candida albicans* may also cause pancreatitis.

Systemic disorders The most important systemic disorder causing acute pancreatitis is hemolytic uremic syndrome, followed by sepsis, Kawasaki disease and Henoch-Schönlein vasculitis. Shock from any etiology may lead to pancreatitis by decreasing blood flow with resultant hypoxia. Reye's syndrome may be complicated by severe hemorrhagic pancreatitis. Children with collagen-vascular diseases including systemic lupus erythematosus (SLE), juvenile rheumatoid arthritis and polyarteritis nodosa, and inflammatory bowel disease like Crohn's disease and ulcerative colitis may also develop pancreatitis. However, many of these children may also be taking drugs known to cause pancreatitis, as part of the treatment of their primary disease.

Trauma The pancreas is not commonly damaged in blunt abdominal trauma as it is protected to some extent by its intraperitoneal location. Pancreatic damage is usually associated with injury to other organs, especially the liver and spleen. Bicycle handle-bar injury is an important cause of pancreatitis in children. It is important to rule out abuse in such cases. Traumatic pancreatitis should not be missed, as it may cause pancreatic duct transection, which may require surgical intervention.

Drugs are an uncommon but important cause of acute pancreatitis (**Box 1**). Drug-induced pancreatitis can be diagnosed only after excluding other causes of pancreatitis. There is usually an interval of 4–8 weeks between the initiation of treatment and onset of pancreatitis. Some drugs cause pancreatitis by a clear mechanism like inducing hypertriglyceridemia, which in turn causes pancreatitis. Pancreatitis can be reproduced on re-challenge with the same drug. One of the most commonly implicated drugs in children is *valproic acid*. The incidence of valproic acid-induced pancreatitis, however, is quite low.

Gallstones which are the most common cause of pancreatitis in adults, may sometimes cause pancreatitis in children, particularly those with congenital hemolytic anemia like thalassemia, sickle cell anemia, hereditary spherocytosis, etc. This should not be overlooked since endoscopic retrograde cholangiopancreatography (ERCP) may be indicated in such children.

Metabolic causes The important metabolic causes of pancreatitis include cystic fibrosis and familial hyperlipidemia types I, IV and V. Both acute and chronic pancreatitis may be seen in these cases. In hyperlipidemia, serum amylase and lipase levels will be normal and serum triglyceride levels will be more than 1,000 mg%. In cystic fibrosis, pancreatic duct may be obstructed due to viscous secretions, resulting in pancreatitis. Pancreas divisum is a relatively common congenital anomaly of the pancreatic ducts. It is caused by the failure of the ducts of the dorsal and ventral anlagen to fuse during the 5th and 6th week of gestation. Here, a major part of the exocrine pancreatic secretion drains through the accessory

BOX 1 Drugs causing pancreatitis in children

- Valproic acid
- Prednisone
- Isoniazid
- Carbamazepine
- Erythromycin
- Sulfonamides: mesalamine, 5-aminosalicylates, sulfasalazine, trimethoprim/sulfamethoxazole
- Metronidazole
- Stavudine
- Pentamidine
- Didanosine
- 6-mercaptopurine
- L-asparaginase
- Azathioprine
- Methyl dopa.

pancreatic duct of Santorini and the accessory papilla into the duodenum. It is usually asymptomatic, but about 10% of these children may develop acute pancreatitis.

Idiopathic Almost 25% of children with pancreatitis do not have any underlying etiology. They are labeled as having *idiopathic acute pancreatitis*, which is a diagnosis of exclusion. These children may develop recurrent attacks of pancreatitis.

PATHOGENESIS

The following four basic changes occur in pancreatitis, regardless of whether it is acute or chronic disease:

- Proteolytic destruction of pancreatic tissue
- Necrosis of blood vessels resulting in hemorrhage
- Necrosis of fat by lipolytic enzymes
- Associated inflammatory reaction.

Mild disease is characterized by peripancreatic fat necrosis and interstitial edema and the more severe form by intrapancreatic fat necrosis, parenchymal necrosis and hemorrhage. It may derange both endocrine and exocrine functions of the gland. The pancreatic acinar cells synthesize and store digestive enzymes until they are stimulated to secrete them into the ducts. All pancreatic enzymes, except amylase and lipase, are synthesized as proenzymes. The duodenum secretes an enzyme called *enterokinase* which activates trypsinogen to trypsin. Trypsinogen also has the capacity to slowly autoactivate to trypsin. Trypsin plays a major role in the pathogenesis of pancreatitis. It activates most proenzymes that participate in the process of autodigestion. Trypsin also activates prekallikrein to kallikrein which directly activates the kinin system and indirectly causes abnormalities in clotting and the complement system.

CLINICAL FEATURES

Most children with acute pancreatitis present with upper abdominal pain and vomiting. The pain is sudden in onset, with gradual increase in severity and reaches maximal intensity in a few hours. It may radiate to the back. The most common site is the epigastrium, followed by right hypochondrium, periumbilical area, back and lower chest. Pain is aggravated by food intake. Some children may have fever, tachycardia, hypotension, jaundice and abdominal signs like guarding, rebound tenderness and decreased bowel sounds. Many children with severe systemic illnesses causing pancreatitis refuse feeds. Hence acute pancreatitis should be ruled out, if a sick hospitalized child has worsening of clinical status with feed intolerance. Jaundice or elevated transaminases should raise the possibility of biliary tract involvement. Rarely, patients present with ascites or an abdominal mass. Epigastric tenderness is a useful, but nonspecific and unreliable sign. There are two rare clinical signs of hemorrhagic pancreatitis due to extravasation of hemorrhagic pancreatic exudate: Grey-Turner's sign—ecchymoses in the flanks; Cullen's sign—ecchymoses in the periumbilical region. These signs are more commonly seen in adults than children, and indicate a poor prognosis. Clinical features are summarized in **Table 1**.

It is difficult to differentiate sterile from infected acute necrotizing pancreatitis as both may result in fever, leukocytosis and severe abdominal pain. However, the differentiation is vital as the mortality rate in infected acute necrotizing pancreatitis is nearly 100% without intervention. The organism can be identified and appropriate antibiotic started with the help of CT-guided fine-needle aspiration and culture of pancreatic and peripancreatic tissue fluid.

The most important factor that determines management of pancreatitis following trauma is whether or not the pancreatic duct has been disrupted. The child with blunt trauma usually presents with mild epigastric pain, which may become severe as the pancreatic fluid leaks into the surrounding tissues. A high index of suspicion is essential as the clinical presentation can be

Table 1 Clinical features of acute pancreatitis

	Common	Rare
<i>Symptoms</i>	<ul style="list-style-type: none"> • Abdominal pain • Irritability in infants • Anorexia • Nausea • Vomiting 	<ul style="list-style-type: none"> • Jaundice • Fever • Feed intolerance • Respiratory distress

quite deceptive. Serum amylase and lipase will be elevated in most children. A CT scan, or MRI cholangiogram may be a valuable diagnostic tool at this stage. Most of these children respond to conservative management alone. Surgery is indicated if there is disruption of the main pancreatic duct.

Complications

Acute pancreatitis is a self-limited disease and most children make an uneventful recovery. Mortality, if any, is due to complications of systemic illness. Major complications are summarized in **Table 2**. Pancreatic necrosis is a segmental pancreatic infarction which may result in serious complications. Fortunately, it is very rare, seen in less than 5% of adults and less than 1% of children. The risk of pancreatic necrosis increases with vascular leakage. The combination of hypovolemia, inflammation, and high hematocrit decreases pancreatic blood flow resulting in infarction. A contrast-enhanced CT reveals an area of under-perfused pancreatic gland. Pancreatic pseudocysts are rare in children compared to adults. They usually resolve spontaneously and drainage is usually not necessary.

APPROACH TO DIAGNOSIS

It is unfortunate that there is no gold standard for the diagnosis of pancreatitis. The diagnosis is based on a constellation of points in the history, clinical examination, supportive laboratory tests and imaging. Pancreatitis can be diagnosed based on the presence of two of the following:

- Abdominal pain suggestive of pancreatitis
- Serum amylase or lipase levels at least three times the upper limit of normal
- Radiologic evidence of acute pancreatitis.

Most children with acute pancreatitis will fulfill these criteria. However, infants and young children may not complain of abdominal pain. *Serum lipase* level is a very sensitive and specific marker of pancreatitis and considered as the first investigation of choice. Serum lipase will rise within 4–8 hour of onset, peak at 24 hour, and may remain elevated for 8–14 days before normalizing. In renal failure, renal excretion of lipase is decreased and hence it may increase up to twofold above normal. Lipase may leak from the intestine in perforation of the bowel and so it may increase up to threefold above normal.

Serum amylase level was the traditional, standard diagnostic test for pancreatitis. Levels will rise within 2–12 hours of onset, peak within the first 48 hours, and remain elevated for 3–5 days before returning to baseline. Even though it is a very sensitive test, its specificity is relatively low. Studies have shown that about 40% of cases of acute pancreatitis in children could be missed if diagnosis is based on amylase alone. Other causes of high amylase levels include intestinal obstruction, appendicitis, bowel perforation, acute cholecystitis and mesenteric ischemia, all of which come in the differential diagnosis of acute pancreatitis. In pancreatitis due to hypertriglyceridemia, serum amylase may be normal due to

the dilutional effects of the lipemia. Serum amylase reaches adult levels only by adolescence whereas serum lipase reaches adult levels after 1 year of age. Hence, lipase is more useful than amylase to diagnose acute pancreatitis in young children (**Table 3**).

The half life of amylase is relatively short (2 hours) and hence cleared rapidly from the circulation. If a child presents late in the course of the disease, the amylase peak may be missed and is one scenario where acute pancreatitis with a normal amylase occurs. Unlike amylase, serum lipase will be normal in diabetic ketoacidosis and in macroamylasemia. Many patients with pancreatitis have a selective elevation of either amylase or lipase at presentation. Hence, ideally, both amylase and lipase should be measured in patients with suspected acute pancreatitis. However, levels of amylase and lipase do not correlate with the severity of acute pancreatitis or its prognosis. Although not routinely available, serum trypsin level is the most accurate laboratory indicator of pancreatitis.

Complete blood count reveals leukocytosis. Hematocrit may be initially increased due to hemoconcentration. A low hematocrit may indicate hemorrhage or hemolysis. Serum electrolytes, blood urea nitrogen and creatinine help to determine the level of hydration especially in patients with intractable vomiting. Hyperglycemia may be caused by damage to the pancreas resulting in decreased

insulin secretion and increased release of glycogen, catecholamines and glucocorticoids. High serum aspartate aminotransferase (AST) and lactate dehydrogenase (LDH) are suggestive of tissue necrosis. Obstruction of the common bile duct may cause elevation of bilirubin and alkaline phosphatase. Hypoxemia may be caused by ARDS and pleural effusion and pH may be decreased due to lactic acidosis, respiratory acidosis and renal insufficiency.

It is essential to differentiate acute biliary pancreatitis which may require urgent ERCP with biliary sphincterotomy and stone extraction from nonbiliary conditions. If there is a threefold or more increase of alanine transaminase (ALT), biliary pancreatitis should be ruled out. The combination of elevated amylase/lipase and ALT may be more predictive of pancreatitis than elevated amylase or lipase alone. Fortunately, such cases are rare in children.

Role of imaging Plain erect abdominal radiograph may show nonspecific findings in pancreatitis like a generalized or local ileus (sentinel loop), or a colon cut-off sign. Rarely, calcified gallstones or pancreatic calcification may be seen. A chest radiograph may show pleural effusion and, in severe cases, a diffuse alveolar interstitial shadowing suggestive of acute respiratory distress syndrome (ARDS). Abdominal ultrasonography (**Box 2**) and CT scan help to document pancreatitis, determine the severity and detect complications like pseudocysts. They also identify any underlying chronic pancreatitis.

CT scan with intravenous and oral contrast helps to detect pancreatic necrosis which appears as nonperfused areas of pancreatic parenchyma. The presence of air within the pancreatic parenchyma suggests infection in the necrosed tissue. This should be confirmed with percutaneous needle aspiration and culture. MRI is useful in a pregnant adolescent (because of the radiation teratogenicity of CT), those who are allergic to the contrast used for CT, and those with renal failure which may be aggravated by the iodinated contrast. It is superior to CT in the characterization of pancreatic fluid collections. Magnetic

Table 3 Comparison between serum amylase and lipase for diagnosis of pancreatitis

	Amylase	Lipase
Sensitivity	Very high	Very high
Specificity	High	Very high
Time for elevation	2–12 hours of onset	4–8 hours of onset
Duration of elevation	3–5 days	8–14 days
Diabetic ketoacidosis and macroamylasemia	Increased	Normal
Utility in young children	Poor	Good

BOX 2 Ultrasonography (USG) findings in acute pancreatitis

- Enlargement and altered echogenicity of the pancreas
- Dilated main pancreatic duct; common and intrahepatic bile ducts
- Gallstones
- Biliary sludge
- Pancreatic calcification
- Choledochal cysts
- Fluid collections—peripancreatic or cystic.

resonance cholangiopancreatography (MRCP) delineates the bile and pancreatic ducts better than CT and has a higher sensitivity in detecting choledocholithiasis and pancreas divisum.

MANAGEMENT**Medical Management**

Treatment is essentially supportive, with the aim of alleviation of symptoms and prevention of complications. If an etiologic factor is identified, treatment should be directed at it. If the initial assessment is suggestive of mild pancreatitis, a conservative approach is indicated with intravenous fluids and frequent, but noninvasive, observation. No drugs (including antibiotics) are necessary, apart from analgesics. CT scanning is unnecessary unless there is evidence of deterioration. Early management steps are summarized in **Box 3**.

The most important cause of death is shock. Hence, the child's vital signs, urine output and central venous pressure should be monitored and corrected. They should be carefully observed for any signs of early organ failure like hypotension and pulmonary or renal insufficiency. Blood gas measurements and oxygen supplementation are mandatory if child has tachypnea. Children with signs of early organ dysfunction may deteriorate rapidly, and need to be cared for in an intensive care setting. Proper analgesia and intravenous fluids are the mainstay of management. Traditionally, opiates are used because of their potency. As morphine may increase the pressure in the sphincter of Oddi, meperidine 1–2 mg/kg IM/IV is preferred.

Capillary leak syndrome is common in children with severe acute pancreatitis. Hence, they may lose fluids from the vascular compartment. The situation may be aggravated if the stomach is decompressed by nasogastric aspiration. Unfortunately, in some centers, children with pancreatitis are kept fasting even today. Volume expansion is vital, as it provides cardiovascular stability, and also helps to prevent development of pancreatic necrosis. Recent studies have clearly shown that early feeding of patients with pancreatitis is beneficial. Enteral nutrition should commence within 24 hours of admission after fluid resuscitation and pain control. Several studies show that adult patients with acute pancreatitis tolerate jejunal feedings with fewer complications than those given parenteral nutrition. Antibiotics are usually unnecessary unless the child has developed pancreatic necrosis. There is no role for surgery during the initial period of resuscitation and stabilization; it is indicated only if the patient deteriorates due to local complications.

BOX 3 Early management of severe acute pancreatitis

- Meperidine—1–2 mg/kg IM/IV
- Aggressive IV fluid therapy
- Oxygen
- Frequent monitoring of vital signs, CVP, fluid intake output, blood gases
- Frequent monitoring of blood glucose, calcium, ALT, creatinine
- CT scan—indicated in clinical deterioration/septicemia/organ failure
- Early nasogastric feeding.

Abbreviations: IM, intramuscular; IV, intravenous; CVP, central venous pressure; ALT, alanine transaminase.

Hyperglycemia may complicate severe pancreatitis. However, it usually normalizes as the inflammatory process subsides, and blood sugar levels fluctuate widely. Hypoalbuminemia may lead to hypocalcemia which is usually asymptomatic and does not require any specific therapy. However, reduction in levels of ionized calcium may cause tetany. *Gabexate mesilate* is a trypsin inhibitor used to prevent or treat acute pancreatitis in adults. Gabexate infusion may be useful in children also.

Surgical Management

Surgery is usually not required and is limited to debridement of infected necrosed pancreatic tissue. Necrosectomy, if necessary for severe pancreatitis, is usually deferred for at least 2 weeks. In the rare instance of mild gallstone pancreatitis, cholecystectomy should be performed as soon as the child has recovered, but before the child is sent home. Abscess can be managed with intravenous antibiotics and external drainage. Surgery or endoscopic stenting may be necessary for traumatic rupture of the pancreatic duct.

CHRONIC PANCREATITIS

Chronic pancreatitis is a painful, destructive, inflammatory disease characterized by progressive fibrosis that leads to irreversible destruction of pancreatic tissue, culminating in exocrine and endocrine insufficiency. Histologic changes include irregular fibrosis, acinar cell loss, islet cell loss and inflammatory cell infiltrates.

ETIOLOGY

In children, chronic pancreatitis is usually caused by genetic diseases such as cystic fibrosis, hereditary pancreatitis or may be idiopathic (**Table 4**). This is in contrast to adults, in whom it is usually due to chronic alcoholism or is idiopathic.

Chronic pancreatitis may be secondary to mutations of several genes. Hereditary pancreatitis is an autosomal dominant disease due to mutations in the trypsinogen gene *PRSS1* that cause premature conversion of trypsinogen to trypsin. These children become symptomatic at a very young age and there is a high-risk of developing pancreatic cancer. *SPINK1* mutations are a common cause of tropical pancreatitis (TP). Severe homozygote mutations of the *CFTR* gene cause cystic fibrosis.

CLINICAL PRESENTATION

The most common presenting symptom of chronic pancreatitis is abdominal pain. A characteristic feature is the almost instantaneous aggravation of pain by food. Although food may also aggravate the pain of peptic ulcer, there is usually a much longer interval between the meal and the pain.

Nausea, vomiting, anorexia and weight loss are common in chronic pancreatitis. Weight loss is secondary to decreased caloric intake due to the fear of exacerbating the abdominal pain. Malabsorption, which occurs if enzyme secretion is reduced to less than 10% of normal, and uncontrolled diabetes may also contribute to weight loss. Such severe weight loss never occurs in other painful abdominal conditions like peptic ulcer. The combination of chronic upper abdominal pain and severe loss of weight should always alert the clinician to the possibility of an underlying chronic pancreatic disease.

DIAGNOSIS

Chronic pancreatitis can be diagnosed by histologic or morphologic criteria alone or by a conglomeration of morphologic, functional and clinical findings. Functional abnormalities alone are not diagnostic of chronic pancreatitis because these tests do not differentiate chronic pancreatitis from pancreatic insufficiency

Table 4 Causes of chronic pancreatitis

Hereditary pancreatitis
<ul style="list-style-type: none"> • CFTR mutations • SPINK1 mutations • Shwachman-Diamond syndrome
Metabolic causes
<ul style="list-style-type: none"> • Types I, IV and V hyperlipidemia • Hypercalcemia • Chronic renal failure
Autoimmune
<ul style="list-style-type: none"> • Inflammatory bowel disease • Autoimmune chronic pancreatitis • Sjögren syndrome-associated chronic pancreatitis
Obstructive
<ul style="list-style-type: none"> • Pancreas divisum • Duct obstruction due to tumors
Miscellaneous
<ul style="list-style-type: none"> • Tropical pancreatitis • Fibrocalculous pancreatic diabetes • Postirradiation • Idiopathic.

Abbreviations: CFTR, cystic fibrosis transmembrane conductance regulator; SPINK1, serine protease inhibitor Kazal type 1.

without pancreatitis. Fecal elastase 1 (< 200 µg/g of stool) and MRCP are two noninvasive pancreatic function tests useful in this condition.

TREATMENT

Treatment depends upon the stage and etiology of chronic pancreatitis. It is similar to that of acute pancreatitis during the early phases characterized by discrete episodes. Intractable abdominal pain is the most distressing feature of CP. Treatment may be initiated with paracetamol, but most patients will ultimately require narcotics, resulting in the risk of narcotic addiction. Endoscopic, surgical and nerve block therapies have been tried in children with intractable pain.

Pancreatic enzyme supplementation helps restore digestive function as much as possible. Being proteins in nature, pancreatic enzymes may be destroyed by gastric HCl. This may be prevented to some extent by prescribing a proton pump inhibitor (PPI). Prolonged use of mega doses of pancreatic enzymes (> 6,000 units lipase/kg/meal) may culminate in a rare complication called *fibrosing colonopathy* resulting in formation of strictures in the ascending colon. Even though free radicals may play an important role in the pathophysiology of pancreatitis, the role of antioxidant therapy is still not clear. Another major problem is the development of diabetes as a sequel to destruction of the pancreatic islet cells.

TROPICAL PANCREATITIS

Tropical pancreatitis is a juvenile form of chronic calcific nonalcoholic pancreatitis prevalent almost exclusively in the developing countries of the tropics. In India, the highest prevalence is in the southeastern part of Kerala state. TP is almost exclusively seen in under-privileged children with severe PEM, associated with high levels of circulating free radicals which can damage the pancreas. The staple diet of these patients is cassava (*tapioca/Manihot esculenta*), a tuber rich in carbohydrates but very poor in proteins (0.4 g%) especially the sulfur containing amino acids methionine and cysteine. It contains toxic cyanogenic glycosides like linamarin and methyl linamarin (lotaustralin), which have been implicated in the pathogenesis of TP. Many recent studies have identified genetic markers especially mutations of SPINK1 and N34S.

Chronic severe abdominal pain in childhood, followed by diabetes in an emaciated teenager is the classic presentation. The radiologic demonstration of extensive pancreatic calcification clinches the diagnosis. Management includes control of diabetes with oral hypoglycemic agents and/or insulin. Long-term analgesics and surgery may be required for intractable pain.

IN A NUTSHELL

1. Acute pancreatitis is relatively rare in children, but early diagnosis depends on strong clinical suspicion.
2. Infections, trauma and drugs are the most important predisposing factors.
3. Always exclude accidental/nonaccidental trauma in children with idiopathic recurrent pancreatitis.
4. Rule out HIV infection in children with unexplained pancreatitis as the disease as well as its treatment may result in pancreatitis.
5. There is no gold standard for the diagnosis of pancreatitis, but lipase and amylase are still useful laboratory markers.
6. In the diagnosis of pancreatitis, serum lipase is as sensitive but more specific than amylase.
7. Antimicrobials have no role unless patient has infected necrosis.
